by

Devin N. Lebrun

Dedicated to my father, Denis Lebrun, for his love and support.

ACKNOWLEDGMENTS

I would like to thank my advisor, Dr. Johannes van Oostrom, for all the advice he has given me on realizing my career goals. I knew what I wanted, but he helped me get from there to here and now onto somewhere great. He endured barrages of scatterbrained, unintelligent questions and always surfaced with the answers I needed.

I am grateful to Dr. Charlene Krueger for allowing me to share in her research and express my gratitude to Dr. Krueger, Dr. van Oostrom, and the College of Nursing for providing me with funding throughout my research. I would also like to thank Kelly Spaulding, John Hardcastle, Dr. JS Gravenstein, Dr. Richard Melker, and Dr. John Harris for their support in various areas.

Words cannot describe my appreciation for my parents. They have taught me to be determined, self-motivated, and not afraid of failure. I thank Linnea, for her companionship and assistance throughout the past 6 years. Finally, thanks go to all my friends for keeping me from doing something stupid (well, more stupid).

ANALYSIS OF NEONATAL HEART RATE VARIABILITY AND CARDIAC
ORIENTING RESPONSES

By

Devin N. Lebrun

August 2003

Chair: Johannes H. van Oostrom

Major Department: Electrical and Computer Engineering

We have applied signal-processing methods to evaluate the clinical significance of heart rate variability (HRV) features, assess developmental changes in HRV, evaluate vagal tone, and demonstrate a cardiac orienting response (COR).

The study is based on a sample of 28 low-risk premature newborns randomly assigned to one of two groups. Group 1 is exposed to an auditory stimulation beginning at 28 weeks GA and Group 2 begins exposure at 32 weeks GA. An eight-minute ECG recording is taken once a week from 28-34 weeks GA. The recordings were analyzed in the time and frequency domain using MATLAB. Extracted features are used to classify developmental changes in HRV across individuals and subject groups. In addition, we have used a staggered grouping approach to separate cardiac orienting responses from reflexive responses.

At the conclusion of this thesis, the sample size ($n=5$) was not large enough to elicit any developmental trends in GA. However, we were able to extract useful features to

describe developmental changes in HRV and we have acknowledged Empirical Mode Decomposition as an effective measure of a cardiac orienting response. Also, we have identified numerous exogenous interactions and perturbations which can interfere with the baroreceptor and chemoreceptor responses controlling HRV. These interactions were not considered in the original design of the study but will now be considered during final analysis.

CHAPTER 1 INTRODUCTION

The premature infant faces many obstacles beyond the control of present day medical science. Since the loss of the “in utero environment” strips the premature infant of the most advantageous setting for growth and development, it is increasingly important for medical science to reach a greater understanding of the developmental changes during this final trimester. Survival rates of neonates will continue to increase as science begins to elucidate more regarding this crucial period of development. In general, scientific advancements are predicated upon a divide and conquer approach. It is important to embrace the past discoveries as background for future research. Therefore, this study expands upon a preliminary study conducted by the Principal Investigator (PI), Charlene Krueger, Ph.D, ARNP. The findings of the preliminary study indicate that the analysis of heart rate variability (HRV) can provide significant insight into the development of the premature and fetus’ autonomic nervous system (ANS). In collaboration with Dr. Krueger, the current study moves from the comforts of the uterus to the premature infant’s continuing development in a Neonatal Intensive Care Unit (NICU) setting.

About a third of premature births occur for no apparent reason and with little or no warning. The list below describes some known causes of premature birth [1,2]:

- Pre-eclampsia, occurring in about 1 in 14 pregnancies, causes around a third of all premature births.
- Pregnancies involving multiple fetuses are likely to end early.
- Stressful events can elicit the mother into a premature labor.

- An infection involving the uterus may trigger an early delivery.
- The mother's water may break early, starting the delivery process.
- A shortage of oxygen exchange to the placenta may cause a doctor to advise a caesarian section.
- Malnutrition or chronic diseases, including high blood pressure, diabetes, kidney disease and hypothyroidism can cause premature births.

Regardless of the cause for an early birth, premature infants are commonly highly dependant upon the continuation of breathing support, intravenous nutrition, intravenous antibiotics, and phototherapy. These infants are frequently placed in NICUs, which specialize in caring for the very young and/or very small. The neonate's high dependency upon medical interventions demonstrates a need to establish criteria regarding his or her efficiency at regulating homeostasis. Homeostasis is the maintenance of equilibrium in a biological system by means of automatic mechanisms, which counteract influences trending toward disequilibria. It involves constant internal monitoring and regulating of numerous factors, including oxygen, carbon dioxide, nutrients, hormones, and organic and inorganic substances. Due to homeostatic controls, the concentrations of these substances in body fluid remain unchanged, within limits, despite changes in the external environment. Efficient regulation of these parameters is necessary to support life, on all levels. Therefore, the ability to evaluate homeostatic controls would facilitate the decision process leading to the neonate's discharge from the unit. The events surrounding the control of homeostasis will be discussed further in Chapter 2.

We hypothesize that an index of HRV will provide sufficient insight into the maturity level of the neonate's ANS. In turn, this will provide us with information regarding the ability of the neonate to control events of homeostasis. In a study by

Chatow et al, increasing conceptual age, CA, or gestational age, GA, is correlated with neonatal autonomic control. Chatow used a power ratio, discussed in Chapter 2, which was assumed to reflect the sympathovagal balance of the ANS [3]. In a study of the fetal baboon, Stark et al. suggest that “Sequential decreases in fetal heart rate, increases in RR interval (RRi) variability and increases in changes in RRi and Δ RRi with age imply an overall maturation in autonomic cardio-regulatory control processes. Increases with gestation of high frequency components of variability are compatible with enhanced parasympathetic modulation of the fetal heart rate” [4]. This thesis will attempt to expand upon these studies to examine developmental changes, cardiac orienting responses, and to introduce a maturation index based on time and frequency-domain analysis of neonatal HRV. Current methods of frequency domain analysis tend to center around one method of analysis. Therefore, new methods of analysis will be constructed as a result of combining the most functional signal processing tools described in recent literature. This thesis will explore and compare a variety of spectral analysis methods and focus on those methods deemed most clinically significant. In addition, we will parallel techniques used to examine the frequency spectrum of HRV with time-domain techniques to provide a complete clinical evaluation of each patient and grouping.

CHAPTER 2
AUTONOMIC NERVOUS SYSTEM AND HEART RATE VARIABILITY

Autonomic Nervous System

The ANS is part of the human central nervous system (CNS). The CNS can essentially be divided into three closely interacting sections: the motor nervous system, sensory nervous system, and autonomic nervous system. The ANS originates from the brainstem at the base of the spinal cord. It includes the nerves, which innervate the smooth muscles of the heart, internal organs, and glands. The ANS is subdivided into the sympathetic (SNS) and the parasympathetic (PNS) systems, which originate from different areas in the brainstem and spinal cord.

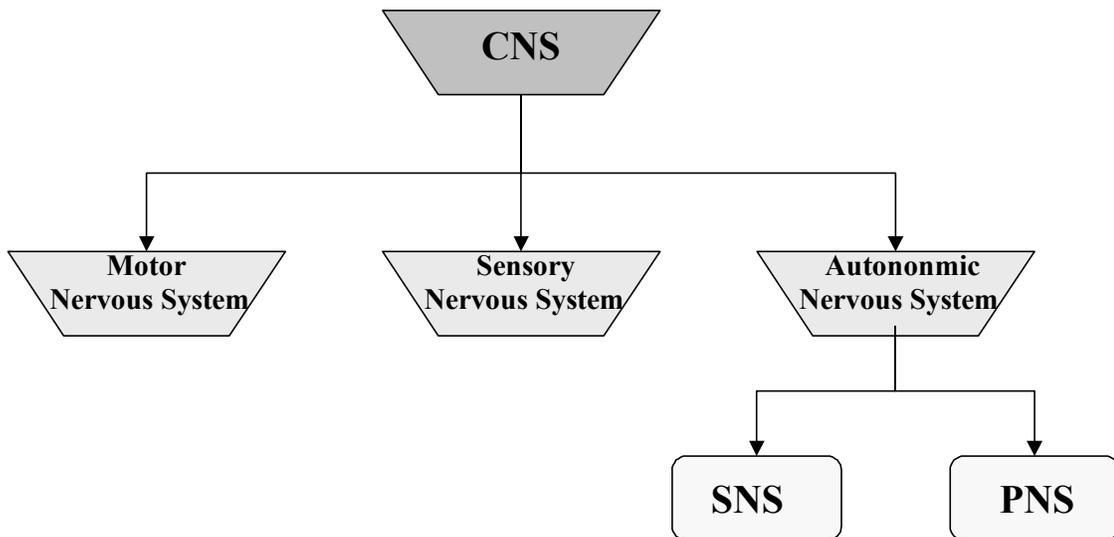

Figure 2-1. The divisions of the central nervous system.

Both systems work simultaneously in an antagonistic nature, with an increased activity in one, inevitably causing a decrease in the other. However, neither substructure of the ANS is ever completely disabled by the response of the other. While both the branches of the ANS serve to regulate the internal organs by stimulating or inhibiting their activity, these two substructures respond to different biochemical transmitter substances [5]. The actions of the PNS are started by the release of acetylcholine. Parasympathetic nerve fibers slow the heart rate, narrow the bronchioles, and cause the release of insulin and digestive fluids. On the other hand, the actions of the SNS are started by the release of norepinephrine. SNS responses include relaxing the tubes of the bronchioles, speeding up the heart, and slowing the digestive tract muscles, while increasing the release of glucose from the liver [5]. Given the broad spectrum of physiological events controlled by the ANS, it is important to establish criteria to evaluate its tone. Past research has indicated, through the measurement of heart rate variability, an inference can be made regarding the functionality of the ANS [3,6,7].

HRV is defined as beat-to-beat fluctuations in heart rate attributed to electrical impulses generated by the sino-atrial (SA) node. The SA node is commonly referred to as the heart's internal pacemaker, and the vagus nerve, or the Xth cranial nerve, inhibits this pacemaker. The PNS influences the SA and AV nodes via the vagus nerve. This influence is produced by release of the neurotransmitter acetylcholine at the vagus nerve endings, which result in the slowing of activity at the SA node and a slowing of the cardiac impulse passing into the ventricles. The SNS has the opposite effect through the release of norepinephrine at the sympathetic nerve endings, thereby increasing the heart rate [5].

HRV reflects the response of the ANS to exogenous or endogenous perturbations. Numerous factors contribute to HRV including blood pressure, temperature, respiration, state of oxygenation, ventilation, biochemical influences of the acid-base balance, and psychological parameters [3]. Continuous changes in sympathetic and parasympathetic neural impulses induce changes in heart rate and cause oscillations around the mean, defined as HRV. By studying heart rate variability, an opportunity exists to study cardiac dynamic behavior and functionality of the ANS. Since the Autonomic Nervous System's control of heart rate is dynamic and nonlinear, it is necessary to explore viable parameters, which can be used to access the causes of these beat-to-beat fluctuations. This thesis will address time-domain, linear frequency-domain, and nonlinear frequency-domain characteristics of the HRV. Thus the framework for the study has been set, with an attempt to answer each of the following questions:

1. What clinically significant features can be extracted from HRV?
2. What are the developmental changes in HRV?
3. Can we establish criteria to assess vagal tone?
4. Can the premature infant learn or demonstrate a cardiac orienting response, and does HRV change as learning emerges?

Developmental Changes

Immediately following birth, the heart rate is extremely sensitive to physiological state of the infant. The developmental changes in HRV are hypothesized to indicate a change in the parasympathetic tone. While early fetal life indicates a strong dependence on the SNS, these two systems trend toward an equal balance in the term infant [3]. This thesis assumes a parallel between the fetus and the premature infant. The developmental changes in heart rate variability can be measured through time and frequency domain statistics. Developmental trends of HRV will be measured across subject groups and

gestational age. Time and frequency domain indexes will be used to assess maturation of the neonate's ANS, or ability to regulate homeostasis.

Vagal Tone and Homeostasis

Cardiac vagal tone is a construct that describes the functional relationship between the brainstem and the heart. Cardiac responses to brief low intensity stimuli should be deceleratory, indicating receptiveness to incoming stimuli. Cardiac responses to sustained stimuli should be acceleratory, indicating attempts to shut it out [8]. Vagal tone reflects individual differences in degrees of influence of the vagus on the heart rate. High vagal tone is associated with the ability to attend selectively to stimuli and maintain attention during a task, the ability to maintain homeostatic integrity, and infers healthier ANS functioning over the long-term.

Homeostasis is primarily maintained by the PNS and provides a physiological framework for the development of complex behaviors. Therefore infants with a high parasympathetic tone are more efficient regulators of homeostasis than those dominated by sympathetic responses [6]. The PNS is primarily responsible with coordinating the life-support process, which intrinsically provides maximum growth and restoration of the body's tissues and organs [9]. More effective regulation of homeostasis may be an important factor underlying the relationship between high resting vagal tone and favorable neurobehavioral development [6]. Moreover, vagal stimulation controls life-support processes including sucking, swallowing, thermoregulation, and vocalization [9]. The search for an accurate measurement of parasympathetic and sympathetic tone has only begun to express its value. This thesis is anticipated to contribute to the comprehension of these physiological parameters.

Cardiac Orienting Response

The existence of a cardiac orienting response (COR) suggests that HRV includes a neurogenic response. The deceleratory parasympathetic component is provided by the bi-directional vagus nerve, which includes both efferent and afferent fibers. Efferent fibers originating in the brain stem terminate on the SA node. Vagal afferent fibers originate throughout the heart and project to the nucleus tractus solitarius [10]. These fibers serve as a continuous response and feedback mechanism between the heart and the brain, facilitating regulation of cardiac function. Porges et al. suggest that the time course of the response, the effects of neural blockades, and studies with clinical populations support this theory. As noted by Porges the heart rate deceleration associated with the cardiac orienting response is rapid and usually returns rapidly to baseline. Also, the latency characteristics of the cardiac orienting response are similar to the opto-vagal, vaso-vagal, baroreceptor-vagal and chemoreceptor-vagal reflexes [8]. Since short latency heart rate reactivity is mediated by the vagus nerve, the magnitude of the cardiac orienting response may be an index of vagal regulation.

Respiratory Sinus Arrhythmia

Respiratory sinus arrhythmia (RSA) has long been used to estimate vagal tone because of its association with PNS. RSA results from increases in vagal efference during exhalation, which decelerates heart rate, and decreases in vagal efference during inhalation, which accelerate heart rate. Recently, the accuracy of the correlation between RSA and vagal tone has been questioned because it only partially accounts for the beat-to-beat fluctuations of the heart [10]. This thesis will address RSA as a possible criterion to extract vagal tone, but due to the nature of the study will not pharmacologically prove

the efficiency of this technique. However, since RSA accounts for a significant amount of variability in heart rate, it is impossible to completely ignore this aspect.

CHAPTER 3 PRELIMINARY RESULTS AND STUDY PROCEDURES

Preliminary Findings

In a preliminary study by the principal investigator [7], cardiac activities during two consecutive quiet periods of 16 healthy fetuses were measured. The exploratory phase used a repeated measures design to follow the normative changes in fetal HRV between 28-34 weeks. Changes in HRV were explained by normalized power shifts in the Fast Fourier Transform (FFT) frequency spectrum. A multi-group pretest-posttest experimental design determined whether 28-34 week-old fetuses would become familiar with a rhyme, recited by the maternal parent. Developmental changes in the HRV frequency spectrum occurred in a nonlinear fashion and individual differences were apparent. The total power diminished significantly with increasing gestational age. Furthermore, the study provided conclusive evidence that the 28-34 week old fetus was capable of responding to a nursery rhyme their mother recited aloud. The response to the nursery rhyme was described by a shift in the power of HRV frequency spectrum to the high frequency bands, which is synonymous with an increase in parasympathetic activity. This conclusion parallels all hypothesized learning capabilities of the premature infant.

The testing sessions for the preliminary study utilized a recording of a rhyme spoken by an unfamiliar female, which insured the fetuses' reactions would be elicited by familiarity with the acoustic properties of the rhyme. Once learning was detected, ongoing interactions between learning, movement and HRV were detected. A

nonparametric signed test was used to compare differences across time. The preliminary study revealed a significant downward trend in fetal movement and an upward trend in a high (.17-.40 Hz) frequency once a cardiac orienting response or learning was identified. Since the subject size was small, there exists a need for a more expanded and complete study before any conclusions can be drawn. However, the findings of the fetal study provide the framework for this expanded research, conducted in collaboration with the PI of the preliminary study.

Proposed Study

A convenience-based sample of 28 low-risk premature newborns admitted to the NICU at Shand's Teaching Hospital are recruited, in blocks of four, and randomly assigned to one of two groups. The target age for admission into the study is 27-28 weeks post-conceptual age. Group 1 will begin exposure to the nursery rhyme at 28 weeks and those in Group 2 will begin exposure at 32 weeks. Staggering the groups shall assist in determining whether an orienting response was a function of learning or simply a reflexive response to presentation of the rhyme. All subjects will be excluded from analysis if they are subject to one or more of the following:

- An abnormal head ultrasound
- A sensorineural hearing loss
- A confirmed prenatally transmitted virus/bacterial infection
- Cardiac abnormalities

Table 3-1. Organization of Recitation and Test Sessions

Group	28 weeks	29 weeks	30 weeks	31 weeks	32 weeks	33 weeks	34 weeks
1	Recite Test						
2	Test Only	Test Only	Test Only	Test Only	Recite Test	Recite Test	Recite Test

Recitation Sessions

The mother of the infant will complete a recording of a nursery rhyme, identical to that presented in the preliminary study. The nursery rhyme, taking approximately 15 seconds to recite, will be played 3 consecutive times to provide the infant with 45s of auditory stimulation. The maternal recitation sessions will occur once in the morning and again in the evening, each day; Group 1 will begin at 28 weeks and Group 2 at 32 weeks of age. The purpose of the recitation session is to introduce the neonate to the rhyme using a familiar voice.

The nursery rhyme will be presented once the premature infant is judged to be in a state of active sleep and at least fifteen minutes following a feeding [11]. Between 28-34 weeks post-conceptual age active sleep accounts for approximately 70% of the entire sleep-wake cycle [12]. Learning in the normal newborn, can occur during periods of active sleep [13,14] and have occurred in the fetus during quiet periods of their quiet-activity cycle [7]. Criteria established by Thoman and Whitney [15] and Holditch-Davis [12] will be used to detect active sleep. The subject is in an active sleep state when:

- Eyes closed
- Respiratory rate under 25 breaths per minute
- Limited movement of extremities

Subjects will be monitored at the same time each week because of potential circadian influences on heart rate patterns and movement [16]. A hospital log of recitation times and the time since the neonate's last meal will be kept because variations related to unexpected changes in hospital routines are expected. These recitation sessions will be completed entirely separate from the testing session described below.

Test Sessions

Each group will undergo a 480 second ECG recording during each test session. Once more, the criteria established by Thoman and Whitney [15] and Holditch-Davis [12] will be used to detect active sleep before the test session begins. The ECG recording will be divided into two stages. The first stage of this study incorporates an exploratory, two-group pretest-posttest subject set which will be used to methodologically replicate the findings from the preliminary study in the premature newborn during a similar developmental time period (28-34 weeks post-conceptual age). The exploratory design will follow specific changes in HRV, measured by time series analysis, power spectral analyses, and time dependant spectral analysis over 28-34 weeks post-conceptual age. A 240-s window separated from the delivery of the auditory stimulus and commencement of the second phase will be used to represent developmental changes in HRV. It is hypothesized that developmental changes in HRV will occur in a decreasing, nonlinear fashion over 28 to 34 weeks gestational age. Two interactions (gestational age vs. gender and gestational age vs. group assignment) will be included in the mixed general linear model. The mixed model allows for the individual random effects when estimating fixed population effects [17].

During a second period of confirmed active sleep, a two-group pretest-posttest experimental design will be used to document when a cardiac orienting response to a presented nursery rhyme first occurs, and how movement and HRV change once it is detected. Again, a nursery rhyme identical to that presented in the preliminary study will be used. An unfamiliar, English-speaking female performs the recitation of the nursery rhyme used in these test sessions. To avoid additional exposure to this unfamiliar voice, this person will not be in attendance for presentations of the rhyme to the infant. The

nursery rhyme takes approximately 15 seconds to recite, and will be repeated 3 consecutive times to provide the 45s window of auditory stimulation. The testing sessions using the unfamiliar recording of the nursery rhyme will occur once a week for both groups from 28-34 weeks post-conceptual age.

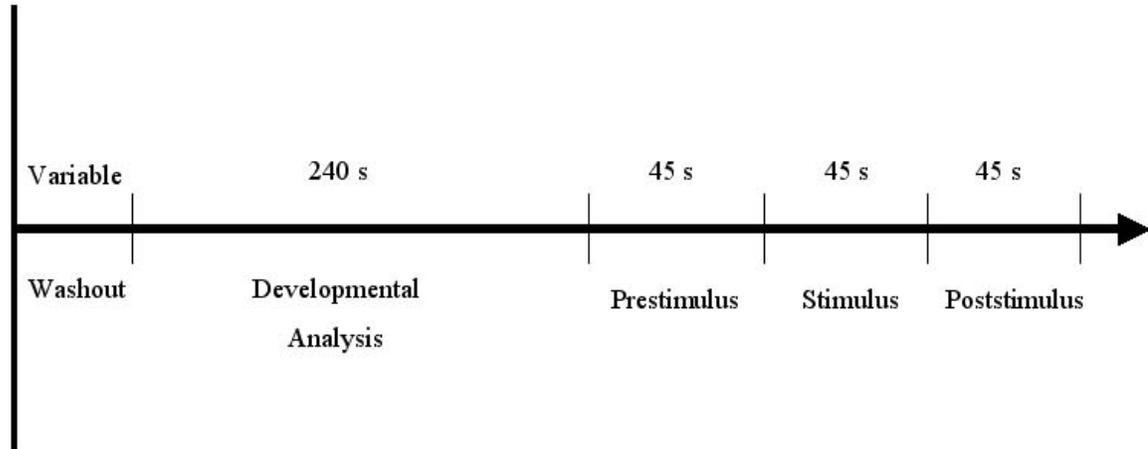

Figure 3-1. Time-line for the windowing of test data.

This second stage will be separated into three 45s windows, in which statistical analysis of heart rate variability will be individually analyzed. The first window will be used to detect the baseline state of the infant before the presence of any auditory stimulation. The second window, immediately following the first, chronologically corresponds to the recitation of the nursery rhyme. This window will be used to observe time and frequency domain changes in HRV, which may reflect the hypothesized COR. A third consecutive window will be used to examine how the neonate responds after the auditory stimulation has been removed from the environment. The third window will be used to verify that an observed COR response is not merely a result of coincidental changes in HRV. In addition, a count of movements will be recorded onto the hospital log during each test session. Our hypotheses pertaining to a COR suggest, (a) over 28-34

weeks of gestational age, it will take 2-5 weeks of recitation to detect and maintain a cardiac orienting response in each subject and (b) once a cardiac orienting response has been observed, subsequent testing session will demonstrate a trend of movement counts and specific HRV characteristics.

CHAPTER 4 TESTING

The rhymes will be played over a 2.5-inch Radio Shack speaker positioned 20 cm from the infant's ear. Both versions of the rhyme (maternal and unfamiliar) will be delivered at 55 dB (± 5 dB) as measured by a Bruel & Kjaer sound level meter (2239) using A-weighted sound pressure levels [18]. This decibel level is just below the normal levels of conversational speech (58-60 dB) and is significantly lower than the background sound levels reported in the literature (70-80 dB ± 20 dB) for NICUs [19,20]. The decision to present both versions of the rhyme (maternal and unfamiliar) at 55 dB (± 5 dB) was based on preliminary findings in the premature fetus where a sound level of 75 dB was used [7]. This decibel level corrects for a 20-decibel attenuation due to passage of sound through the uterine wall [21], bringing the sound level down to approximately 55 dB or to just below the level of normal conversational speech (58-60 dB). The study will record decibel levels at the infant's ear prior to presentation of the maternal and unfamiliar rhyme. In the preliminary study, this sound level (75 dB) did not elicit a cardiac deceleration until a history of recitation of the nursery rhyme had occurred [7].

An RS232 interface from the Agilent Neonatal CMS 2001 neonatal monitor to an IBM compatible computer (Dell Inspiron 8100 Laptop) was constructed to obtain the ECG signal and respiratory rates. The data acquisition program is designed to run in DOS and may be activated from the Windows Desktop of Dell Inspiron 8100 Laptop by double clicking on the "Neonatal Data Acquisition" icon. The C program, originally written by Hewlett Packard (HP), was modified from an earlier version to in order to

record the ECG and respiratory rate. The HP program was initially written to demonstrate that information from their monitors could be transferred and displayed on peripheral devices through RS-232 interfacing. The sample program was only available in a DOS format. Although this format is not optimally user friendly, an extensive user interface was not necessary to transfer the required signals into readable text files.

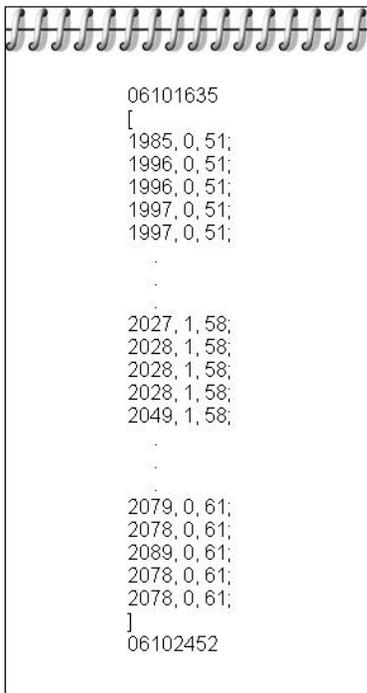

Furthermore, HP uses a complex communication protocol, which makes it desirable to avoid writing an original program. The original program was capable of display the ECG signal on a peripheral monitor, which implies that the ECG information was already being transferred. The program modification involved the following:

- Requesting the respiratory rate signal and displaying the information on the screen.
- Creating a user interface to request the patient number.
- Transferring the requested information to a readable text file.

Before data acquisition can begin, the Agilent monitor must be set to a baud rate of 19200 and the transition must be set to a high to low trigger. If the baud rate or transition is not correctly set, the program will time-out after eight seconds. When the data acquisition program is started the user enters the patient number and is asked to confirm this number before the recording process begins. The program passes a text string, which signifies the rhyme state and allows the user to mark the data when the rhyme is presented and upon completion. The three measurements: ECG, respiratory rate, and the rhyme state are recorded in an ASCII text file labeled with the month, date, hour (in 24h format), and minute (MMDDHHmm.txt) the program is initialized. ASCII was the chosen format for data storage to permit the user to utilize other analysis programs (i.e. Microsoft EXCEL). The parameters are stored in the format directly readable as a MATLAB matrix and can later be separated into three separate vectors. Preceding the

matrix is an ASCII timestamp, which is recorded once the program has finished the initialization process (DDHHmmss), and appended by another timestamp when the program is terminated. These time stamps allow the user to verify the length of the recording.

The program is designed to work with an ECG/Resp module, which will transfer both the ECG and the respiratory rate signal to the Dell Inspiron 8100 Laptop. However, in the absence of the ECG/Resp module it is possible to use only the singular ECG module. This will not record the respiratory signal, but will still record the ECG signal. The first column recorded in the ASCII text file represents the unsigned 12-bit digital values of the ECG signal. The second column contains the information regarding the rhyme state. The final column contains the respiratory rate. The resulting format of the text file is illustrated in the figure below.

Figure 4-1. Example of text file generated from Data Acquisition Program

All columns are recorded at a sampling rate of 500Hz, which was preserved from the HP demo program as the rate information was sent to the screen. This sampling rate, much higher than the 200Hz often described in literature, was preserved to prevent jagged QRS complexes. The column corresponding to the state of the rhyme is initialized to '0', until the 'r' key is pressed and the value changes to '1'. The value remains at '1' until the 'd' key is pressed, which signifies the end of the presentation and returns the value to '0'. When all desired data has been recorded, the user presses the 'q' key twice to exit the program and return to the Windows desktop.

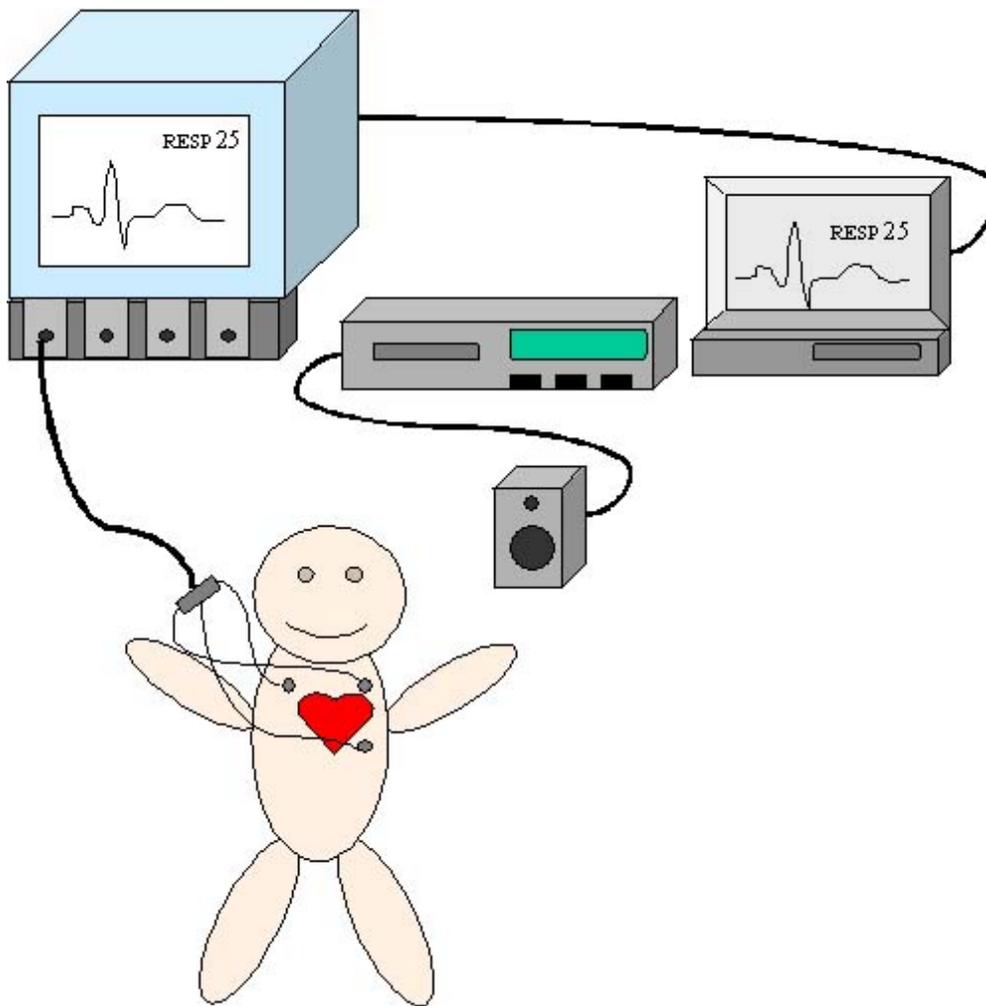

Figure 4-2. The setup for the test sessions.

Figure 4-2 illustrates the equipment setup during the test sessions. A male 25-pin RS232 port in the back of the Agilent monitor is interfaced with the female 9-pin RS232 port Dell Inspiron 8100 Laptop. The RS232 cable provides means of serial communication between the Agilent monitor and the Dell Laptop. The Agilent Neonatal CMS 2001 monitor continually monitors the infant's vital signs, with a standard 3-lead ECG setup. The speakers, connected to the CD CopyWriter Live, are placed 20cm from the infant's ear. This setup is replicated for every test session, regardless of the subject's group number.

CHAPTER 5 QRS DETECTION

Once all data from the testing session is acquired the focus shifts to the data analysis. The first goal is to perform time-series operations, yielding discernable characteristics of the HRV. The HRV is basically controlled by the effect of the vagal and sympathetic influences of the sino-atrial node. Therefore, it seems the best representation of the HRV variability would be expressed as a function of the time intervals between consecutive P waves. However, due to the inconsistent positioning and suboptimal attachment of the infants ECG leads, P waves characteristically have a low signal-to-noise (SNR) ratio [22]. Therefore, in the absence of cardiac arrhythmias, addressed in the exclusion criteria, it seems more reliable to replace the detection of PP intervals (PPi), with RRi. While this may include an extra variable in the analysis of the HRV, it seems trivial compared to the accuracy of the detection of PPi. It is our assumption that variations in the PR intervals will be equal or less than error of detection of the PPi. When considering an error-percentage of P-wave detection greater than the standard deviation of the PR interval and greater than the percent error in R-wave detection, the replacement of PPi with RRi becomes trivial. The occurrence of the following cardiac arrhythmias causes this assumption to fail [23]:

- **ATRIAL FLUTTER** - the atrial flutter waves, known as F waves, are larger than normal P waves and they have a saw-toothed waveform. Not every atrial flutter wave results in a QRS complex because the AV node acts as a filter. Some flutter waves reach the AV node when it is refractory and thus are not propagated to the ventricles. The ventricular rate is usually regular but slower than the atrial rate.

- **ATRIAL FIBRILLATION** - Atrial fibrillation occurs when the atria depolarize repeatedly and in an irregular uncontrolled manner. As a result, there is no concerted contraction of the atria. No P-waves are observed in the EKG due to the chaotic atrial depolarization. The chaotic atrial depolarization waves penetrate the AV node in an irregular manner, resulting in irregular ventricular contractions. The QRS complexes have normal shape, due to normal ventricular conduction. However, the RR intervals vary from beat to beat.
- **VENTRICULAR TACHYCARDIA** - Ventricular tachycardia occurs when electrical impulses originating either from the ventricles cause rapid ventricular depolarization. Since the impulse originates from the ventricles, the QRS complexes are wide and bizarre. Ventricular impulses can be sometimes conducted backwards to the atria, in which case, P-waves may be inverted. Otherwise, regular normal P waves may be present but not associated with QRS complexes. The RR intervals are usually regular.
- **THIRD DEGREE AV BLOCK** - Atrial rate is usually normal and the ventricular rate is usually low, with the atrial rate always faster than the ventricular rate. P waves are normal with constant P-P intervals, but not associated with the QRS complexes. QRS may be normal or widened depending on where the escape pacemaker is located in the conduction system. The result is unrelated atrial and ventricular activities due to the complete blocking of the atrial impulses to the ventricles.

Subjects whose electrocardiogram display any of the arrhythmias listed above are removed from analysis on the basis of violating the exclusion criteria. In conclusion, all ECG time-domain analysis of the HRV will consider RRi rather than the ideal analysis of the PPi for the remainder of the thesis.

The first step in the analysis of the HRV is to extract the RRi from the recorded ECG waveforms. The ASCII text formatted matrix addressed in the data acquisition chapter is read into MATLAB. The result is an N by 3 matrix, with N being the number of samples. This matrix is then separated into 3 vectors of length N. Vector one contains the ECG information; vector two contains the respiratory rate; and vector three contains information regarded the state of the rhyme. Only vector one expresses useful information for analysis of RRi. Figure 5-1 describes the transform of the raw ECG signal to a vector containing RRi.

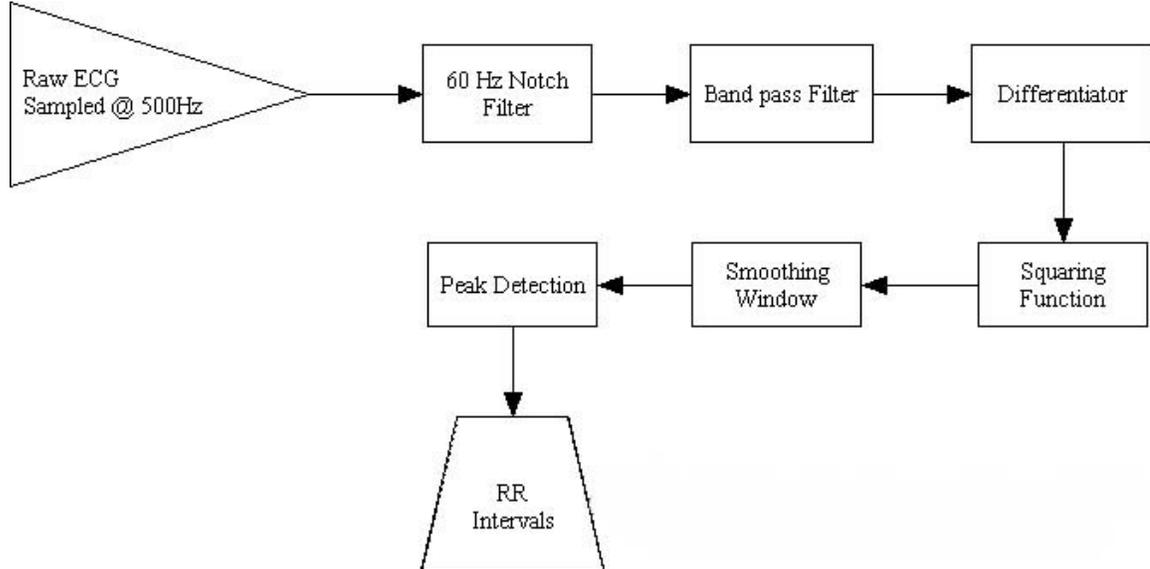

Figure 5-1. QRS detection algorithm

Noise/Baseline Wander

The difficulty in accurate R-wave or QRS complex detection is directly related to the common noise characteristics existing in a raw ECG signal. Noise sources include, but are not limited to: electrode motion, muscle movement, power-line interference, baseline drift, and T-wave interference. Using a method similar to that described by Jiapu Pan [24] we will attempt to improve the SNR of the raw ECG signal and detect the QRS complexes. This process is split into two linear steps and one nonlinear transformation. The first linear process requires filtering the signal with a bandpass filter, which is split into a low-pass and high-pass filter. A low-pass filter with cutoff frequency of approximately 11Hz is first applied the raw ECG signal to remove the low-frequency baseline drift. In addition, the filtered ECG signal is sent through a high-pass filter to remove muscle movement, powerline interference, and T-wave interference. The cutoff frequency of the high-pass filter is approximately 5Hz. This yields a filtered ECG

signal (fECG) containing frequencies of 5-11Hz, which has been described to preserve maximum information regarding the QRS complexes [24].

Low-pass filter:

$$H(z) = \frac{(1 - z^{-6})^2}{(1 - z^{-1})^2}$$

High-pass filter:

$$H(z) = \frac{(-1 + 32z^{-16} + z^{-32})}{(1 - z^{-1})}$$

Filtering with the Pan-Tompkins method described above, yielded only minor improvements to the raw ECG signal. Problems with the above technique arise as a result of the electrode placement differing from subject to subject. In some case, the Pam-Tompkins algorithm removed substantial frequency components of the QRS complex, thereby deteriorating the quality of the signal. Therefore, we need to replace the low and high pass filters described above with a notch and bandpass filter. The nature of the ECG signal calls for the use of an IIR filter. We will explore the Butterworth and Chebyshev filters. Both are high order filter designs, which can be realized by using simple first order stages cascaded together to achieve the desired order, passband response, and cut-off frequency. The Butterworth filter yields no passband ripple and a roll-off of -20dB per pole. However, the flatness of the passband response comes at the expense of roll-off. The Chebyshev filter displays a much steeper roll-off, but is characterized by a significant passband ripple. The Chebyshev filter thereby optimizes roll-off at the expense of passband ripple. Due to the nature of the ECG signal the roll-off frequency of the passband is not as important as the gain in the passband. Therefore, we will use Butterworth filters for all filtering of the raw ECG signal.

Since 60Hz powerline interference is common among electrical signals, we need to construct a notch filter to remove this noise. The notch filter used is a 5th order Butterworth filter with center frequency at 60Hz. The magnitude and phase of this filter is shown in Figure 5-2.

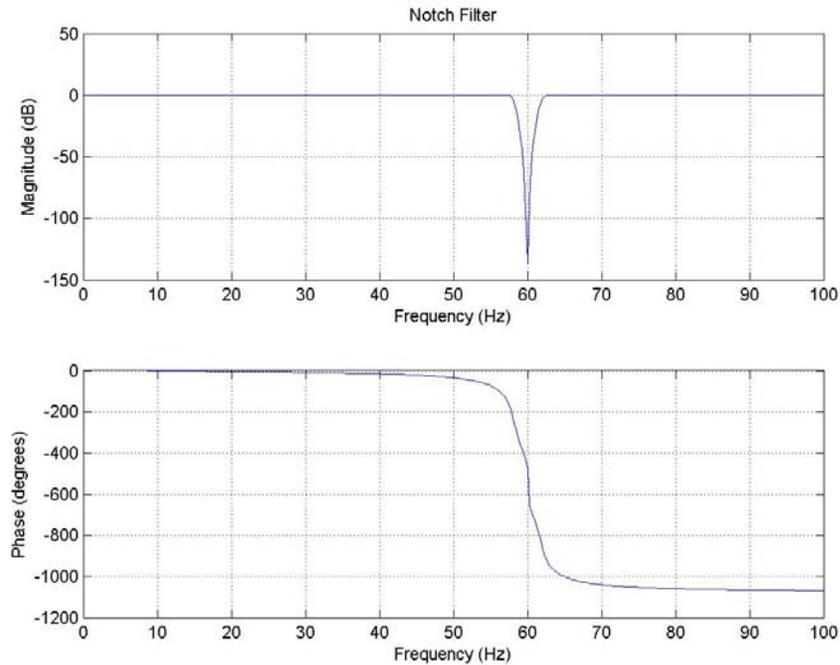

Figure 5-2. Magnitude and phase response of the 60Hz notch filter used to filter the raw ECG signal.

The phase of this filter is essentially linear over the region of attenuation. After the raw ECG signal is passed through the notch filter, it is passed through an 8th order bandpass filter serving to remove baseline wander and high frequency noise; thereby improving the SNR of the raw ECG signal. Both the notch and bandpass filters are implemented using Butterworth filters. As illustrated in the Figure 5-3 below, the phase over the passband region is approximately linear. Keeping the phase of the filter linear over the passband prevents phase distortion in the resulting filtered ECG waveform.

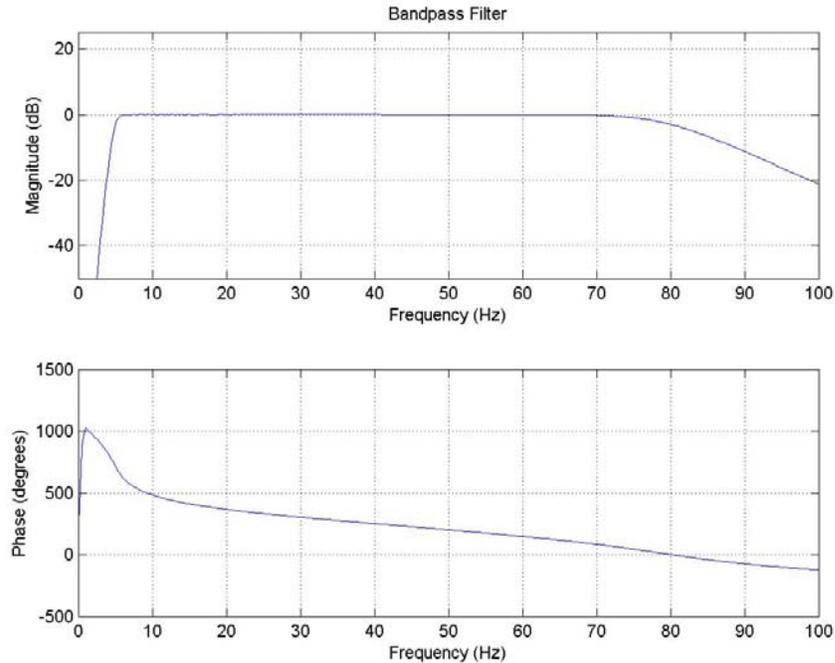

Figure 5-3. Magnitude and phase response of the bandpass filter used to filter the raw ECG signal.

During the recording phase, we obtained ECG recordings that included significant periods where the signal underwent high and low voltage clipping. The clipping resulted in epochs of flat line, thereby making it impossible to detect subsequent QRS complexes. For HRV analysis, a continuous ECG signal is needed. The undesired clipping resulted in extensive signal losses that required considerable epochs of QRS interpolation. It was later discovered that this problem could be overcome by setting the ECG module to filter the signal before it was relayed to the laptop for text conversion. In addition, incorrect electrode placement proved the monitor's default selection of Lead II to be an errant assumption. Lead selection was then delegated to the user before the acquisition program was initialized. After realizing the need to select the "filter" option and correct lead, we were able to attain signals that needed little or no secondary filtering and was not necessary to bandpass filter the recordings. Powerline interference during the passage

from the monitor to the laptop was not completely alleviated and the 60Hz notch filter, described above, was still applied. When the detection phase demonstrated a need for secondary filtering, the bandpass Butterworth Filter, described above, was applied to the signal to conclude the filtering stage of the detection algorithm.

Slope Detection

In parallel with the Pan-Tompkins algorithm, after filtering, the fECG signal is sent through a differentiator yielding QRS complex slope information; this method results in a differentiated version (dfECG) of the fECG. In accordance with Pan [24], we will use a 5-point transfer function to approximate the derivative.

$$H(z) = (1/8T)(-z^{-2} - 2z^{-1} + 2z^1 + z^2)$$

where T is the sampling period.

This transfer function is roughly linear in the region between dc and 100Hz. Therefore it provides a quick approximation of the ideal derivative over the region of interest.

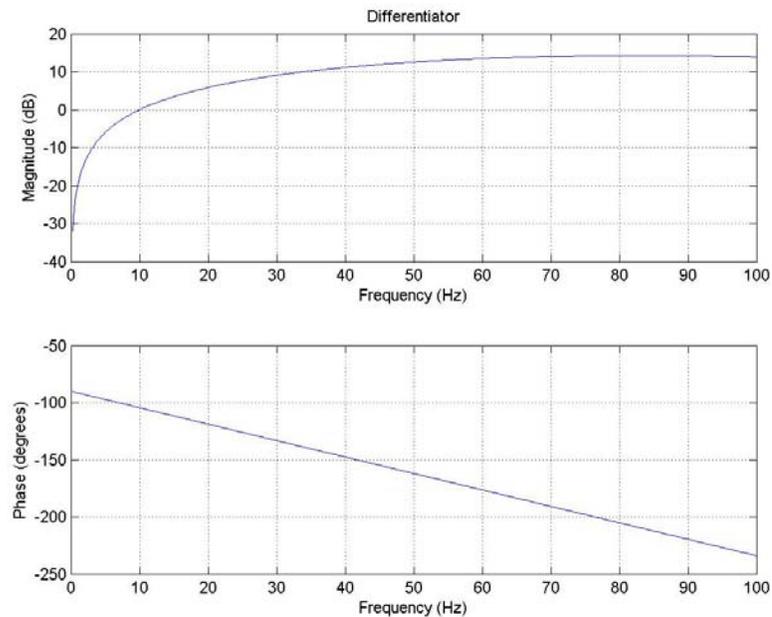

Figure 5-4. Magnitude and phase response of the differentiator function

Following this step, the dfECG signal is passed through a nonlinear point-by-point squaring operator yielding the sdfECG signal:

$$y(nT) = [x(nT)]^2$$

This operation makes all data points positive and supplies a nonlinear amplification of the signal at the higher frequencies. Finally, the sdfECG is smoothed using a ten point averaging function, which produces a signal containing the power information of the ECG waveform's slope, pECG. This reduces the presence of local minima in the sdfECG signal. From this point, the method used for detection of QRS complexes deviates from that used by Pan [24]. Since it is not necessary to perform QRS detection in an online fashion, we have the luxury of determining thresholds using the entire information contained in pECG signal. The threshold limit of the QRS slope detection is set in the following fashion:

$$\gamma = [\max(dfECG^2) + \text{mean}(dfECG^2)] / 2$$

The selection of the current threshold (γ) allows for detection of poorly defined QRS complexes, while distinguishing the R-waves from occurrences of P and T-waves. The threshold is then adjusted throughout the detection process. The following equations illustrates how the threshold is updated:

$$\eta = [\max(dfECG^2(i : i + win)) + \text{mean}(dfECG^2(i : i + win))] / 2$$

where threshold parameter (η) is updated in accordance with the current sample (i) over a user-defined window (win)

$$\delta = \eta - \gamma$$

$$\gamma = \gamma + (\varepsilon * \delta)$$

where δ represents is the threshold difference and includes a memory constant (ϵ) to reduce high frequency noise interference during the update

Once this threshold has been set, it is now necessary to find maximum values during each interval that the signal spends above threshold. The detection algorithm searches the pECG until it reaches a y-value above the threshold. An array is constructed, storing the waveform from this point until the y-value falls below the threshold. The x-value corresponding to the maximum y-value inside this array is stored as a possible QRS complex.

$$QRS = \max(x[n, n + 1, n + 2, \dots, m])$$

where $y[n]$ and $y[m]$ are above the threshold, but $y[n-1]$ and $y[m+1]$ fall below the threshold.

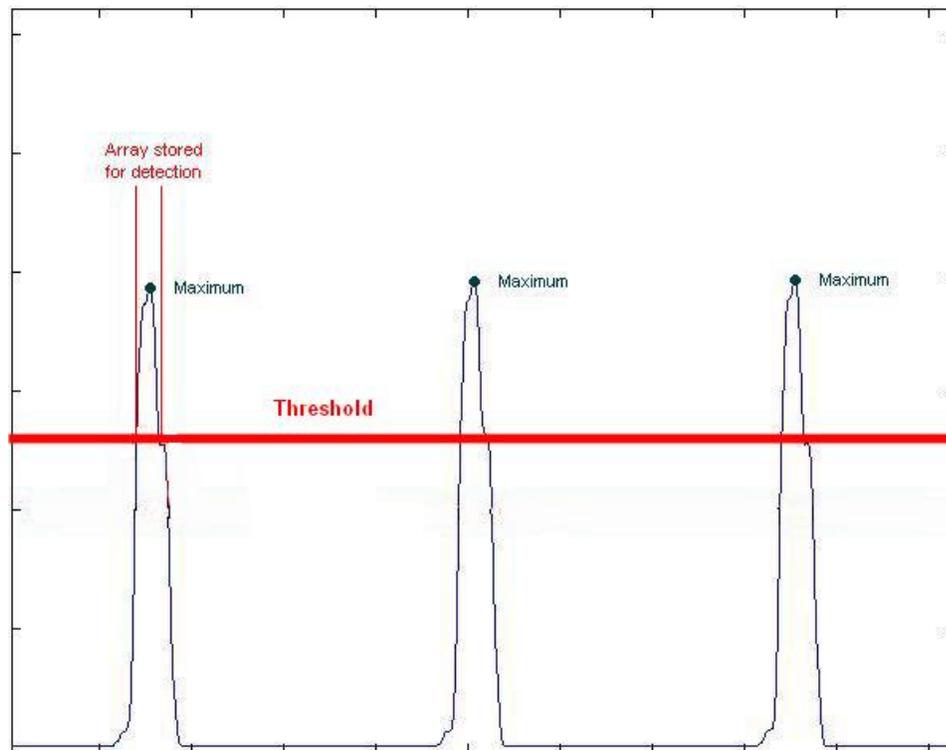

Figure 5-5. Visualization of QRS peak detection

These maximums, or peaks, define the occurrences of possible QRS complexes. If a QRS complex is detected outside the expected range given below,

$$\frac{\text{mean}(RRi)}{\lambda} \leq QRS(k) \leq (\text{mean}(RRi) * \lambda)$$

5. $RR(0) = 0.375\text{s}$ (160bpm)
6. $1 < \lambda < 2$
7. $QRS(k)$ is the detected QRS complex

the algorithm reverts back to the previous QRS complex, adjusts the threshold as follows,

$$\gamma = \frac{\gamma}{\kappa_{\text{threshold}}}$$

$\kappa_{\text{threshold}}$ is a user definable parameter (default = 1.5)

and searches for a new QRS complex. This searchback technique plays a crucial role in preventing high frequency noise contamination, P-waves, and T-waves from being marked as a QRS complex.

If a complex is not found within the expected range after 5 searchbacks, a complex is interpolated as an average of the previous two intervals.

$$QRS(k) = [QRS(k-1) + QRS(k-2)]/2$$

Subsequent detections are stored in a vector of increasing length until the algorithm has operated on the entire pECG signal. In addition, the interpolated detections are stored in a separate vector for further analysis. Units of these vectors are stored according to sample numbers. The vectors are then divided by the sampling rate for unit conversion to the time-domain. Finally, another vector is constructed, which represents a time-based representation of the RRi in the following fashion:

$$RRi = \{QRS(2) - QRS(1), QRS(3) - QRS(2), \dots, QRS(N) - QRS(N-1)\}$$

where N = total number of QRS detections

Figure 5-6 illustrates the final results of the QRS detection algorithm where the QRS complexes are marked in red. This figure also displays a linear interpolation of the RRi waveform corresponding to the detected beats.

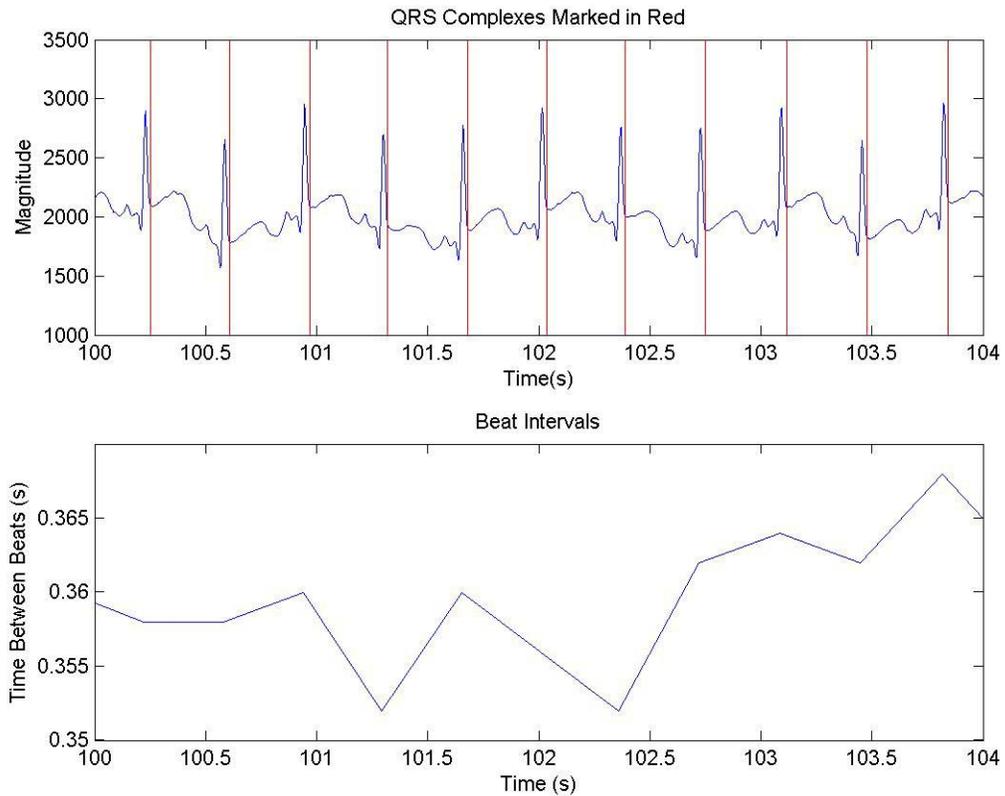

Figure 5-6. Example of detected QRS complexes and beat intervals

The detection is offset from the peaks of the QRS complex due to the intrinsic phase delays of the filtering process. As a result, the delays are consistent throughout each signal and fall out after computing the RRi vector, as follows:

$$\begin{aligned}
 RRi &= \{[QRS(N) - \tau] - [QRS(N-1) - \tau]\} \\
 &= \{QRS(N) - \tau - QRS(N-1) + \tau\} \\
 &= \{QRS(N) - QRS(N-1)\}
 \end{aligned}$$

Outliers

Outliers are ill-defined byproducts of data acquisition systems. There is no rigorous definition of an “outlier”; it is only generally conceived that selectively eliminating inconvenient data points from analysis creates a more robust dataset. Outliers are acknowledged to skew sample means, but tend to have less affect on the median than the mean. For the purpose of this thesis, it is necessary to form a working definition of an outlier.

An outlier is a data point that is an "unusual" observation or an extreme value in the data set.

The lack of a universally accepted definition of an outlier inherently causes a deficiency of objective mathematical processes for outlier recognition. Adding to the complication of outlier detection, RRi datasets are time dependant vectors, rather than independent samples. Therefore, it is essential to add to our working definition of an outlier.

A time dependant outlier is a data point that is an "unusual" observation or an extreme value in the data set, which is not part of a trend in time.

Again, the definition of a “trend” is subjective and needs to be defined for the purposes of this paper.

A trend is two or more consecutive data points, which move in the same general direction within a given statistical range.

These definitions will be used to construct an algorithm to remove time dependant outliers from the RRi datasets. False detections and missed detections result in possible outliers in these datasets. The presence of outliers in the RRi dataset adversely effect both time and frequency domain analysis of HRV. Possible skewed time domain representations of HRV include the mean and standard deviation of RRi windows. In addition, these outliers produce “ghost powers” in the high frequency range of the

spectrum. Not only does this increase the power in the high frequency bands, it skews the power in the low frequency bands. Low frequency bands are of the foremost importance during analysis of HRV in the frequency domain. This will become more evident through discussion in Chapter 6.

Now that the importance of removing outliers has been established, we must construct a mathematically sound algorithm for their removal. Three techniques are explored as possible strategies for outlier detection: direct RRi analysis, slope analysis, and differential analysis. For each of the aforementioned techniques, we will use standard deviation as the exclusion criterion. Since literature is not conclusive for the distribution of RRi datasets, the exclusion criterion is based on normal distribution of the data. The figures below illustrate the RRi distribution and the normal distribution. Visually, the normal distribution seems an accurate estimation of the RRi dataset. We will discuss the validity of this assumption further in Chapter 6.

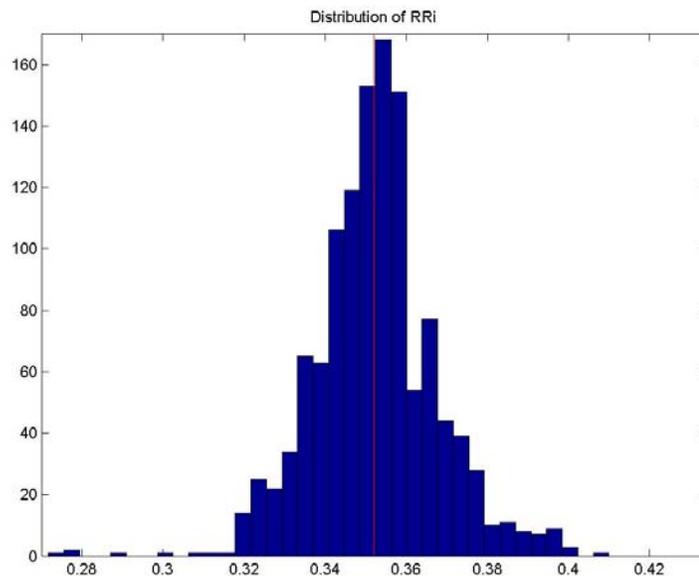

Figure 5-7. Histogram of RRi distribution from one subject.

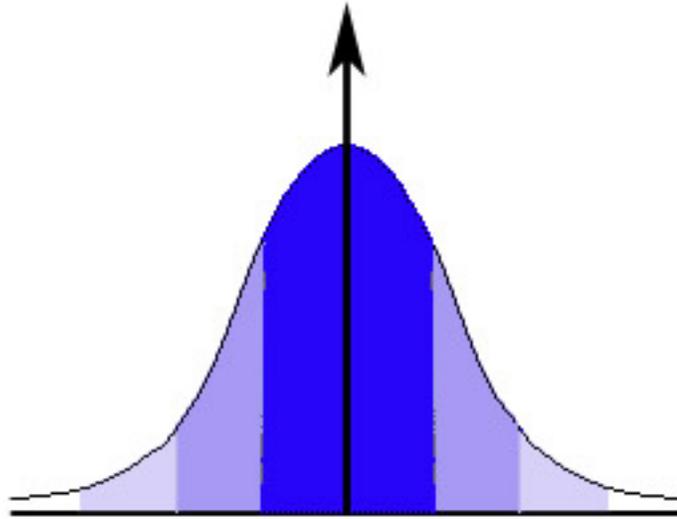

Figure 5-8. Standard deviations of the Normal Distribution

In a normal distribution, one standard deviation away from the mean in either direction on the horizontal axis accounts for around 68 percent of the values in the dataset. Two standard deviations away from the mean includes for roughly 95 percent of the data. Finally, three standard deviations account for about 99 percent of the data [25]. Therefore, we will assume data outside of three standard deviations from the mean to be statistically irrelevant and tag them as outliers unless they are part of a trend.

Direct RRI Analysis

The simplest method of removing outliers would be to examine the RRI dataset directly and remove data that fall three standard deviations above or below the mean.

The following equation is used for outlier detection:

$$outliers = RRI(n) \geq |mean(RRI) + 3 * std(RRI)|$$

for $n = 1 : length(RRI)$

the mean (marked by the black line), situations exist where the upper and lower bound are not symmetrical about the data over a given window. Given all the abovementioned weaknesses, it is necessary to explore a more robust technique to mark the presences of an outlier.

Slope Analysis

In order to correct for the bouncing effect described above, slope information could be used to isolate these occurrences and tag outliers. First, compute the derivative of the RRi dataset, as follows:

$$\partial RRi = \frac{\partial(RRi)}{\partial t}$$

Then, tagging outliers using the same detection method as in the direct analysis:

$$outliers = \partial RRi(n) \geq |mean(\partial RRi) + 3 * std(\partial RRi)|$$

for $n = 1 : length(\partial RRi)$

This algorithm adequately accounts for the removal of the bouncing effect, but we will demonstrate that it is impossible to exclude trends from being tagged. Figure 5-10 is an example of trend which seems to begin abruptly, but is sustained over subsequent intervals. The slope algorithm solves the problems in accordance with the mean and bounce effect, but introduces troubles in excluding trends from being tagged as outliers. Over the course of this trend, only those datapoints whose slope exceeded the bound of acceptance (marked by the green line) would be tagged. No mathematically simple method exists to overcome the flaws in this algorithm. Merely modifying this algorithm to remove the outliers and loop through the process again would serve to completely eliminate the trend. Therefore, for a second time it is necessary to search for a more robust algorithm to tag outliers.

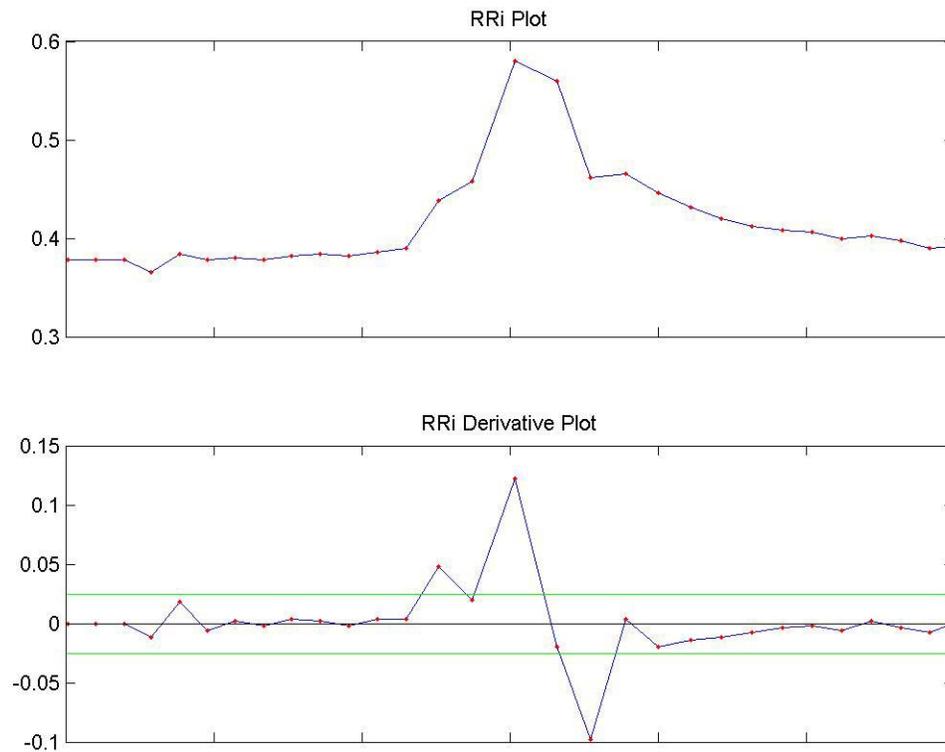

Figure 5-10. Illustrates an RRI trend that would not be preserved using the slope analysis method for tagging outliers.

Differential Analysis

To this point, three problems in the outlier detection process have been identified: mean calculations that deteriorate the symmetry of the acceptance bound, the bouncing effect, and the exclusion of trends. We introduce the differential analysis method as a means, which circumvents all three of these problems. First, a difference vector is constructed as follows:

$$RRi_{diff}(n) = x(n) - x(n-1)$$

for $n = 2 : m$, where $m = \text{length}(RRi)$

$$RRi_{diff}(1) = mean(RRi) - RRi(1)$$

The end product is a vector, which is the same length as RRi. The resulting mean of the difference vector is close to zero, which further implies the data is predominately normally distributed. The difference vector also alleviates the first problem mentioned above. Then, a vector is created using the same exclusion criterion discussed in the previous two subsections. However, using this difference vector alone to tag outliers outside the acceptable standard deviation range is not sufficient. A single outlier in a dataset would produce two datapoints in this difference vector that would be tagged as outliers (n and $n+1$). Being that it is not necessary to perform the outlier removal real-time, we are able to create an additional vector, as follows:

$$\overleftarrow{RRi}_{diff}(n) = x(n) - x(n+1)$$

for $n = 1 : m - 1$, where $m = length(RRi)$

$$\overleftarrow{RRi}_{diff}(m) = mean(RRi) - RRi(m)$$

The same exclusion criterion is used to create a vector containing the outliers. As a result of this computation, a single outlier in the dataset would produce two datapoints tagged as outliers. Since taking the difference of RR intervals backwards through time generates this vector, the two resulting datapoints tagged as outliers would be n and $n-1$. Now, we compare the two difference vectors and note only those values for n , which occur in both. These are the actual RRi datapoints that are separated from the previous and subsequent datapoint by three standard deviations above or below the differential mean. Figure 5-11 is a section of RRi data with trends that would normal be removed using the Direct RRi Analysis method, described above, and a bounce effect.

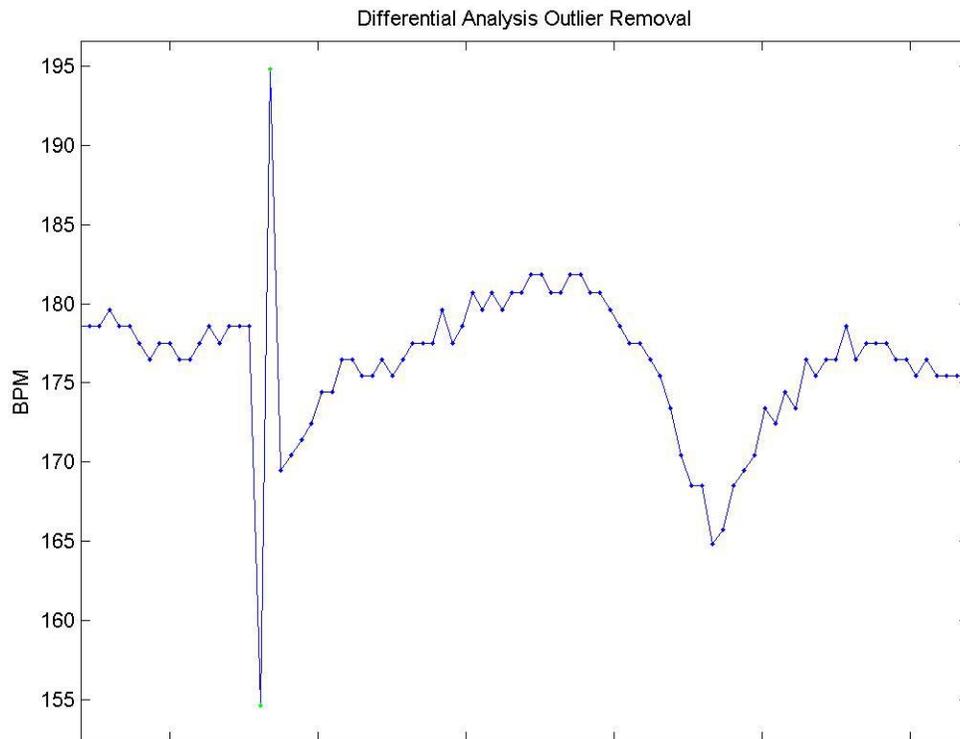

Figure 5-11. Outliers that have been tagged, using the differential method, are marked by a green dot. Shows the efficiency of the method to preserve trend and remove bouncing effects.

In figure above, the points that were tagged as outliers are denoted by green dots. It is now evident that we have constructed a robust method to find and remove outliers, as defined above.

Interpolation

The RR_i vector described above is sufficient for time domain analysis of the HRV. The RR_i vector can also be converted to an instantaneous representation of the heart rate (iBPM). However, there is a problem with using this vector to represent the HRV in the frequency domain. When plotting the RR_i on a time scale, the x-axis must include a cumulative sum of all the preceding RR_i plotted against the RR_i or iBPM. This results in

an unequally sampled representation of the HRV. In order to apply a meaningful power spectral representation of the HRV, the data must be evenly sampled at a known frequency. Many papers using spectral analysis fail to address this topic and there are no universal methods to solve this problem.

Resolving this issue of uneven sampling is essential for spectral analysis. Without addressing this topic, many forms of spectral analysis applied to the RRi would produce meaningless results. The choice of an interpolation method is very important, as it can significantly compromise the integrity of the data. Therefore, we will explore four methods of interpolating between successive data points of RRi:

- Linear Interpolation (LI)
- LaGrange Polynomial Interpolation (LPI)
- Cubic Spline (CS)
- Cubic Interpolation (CI)

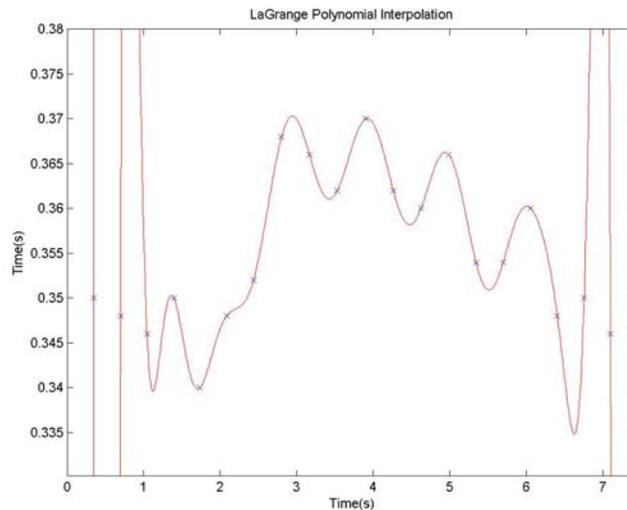

Figure 5-12. LaGrange Polynomial Interpolation

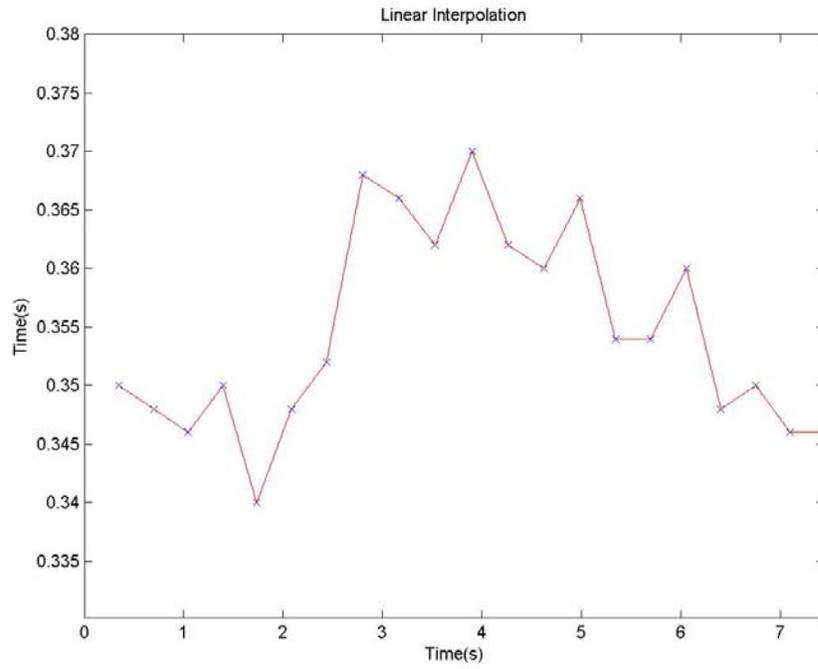

Figure 5-13. Linear Interpolation

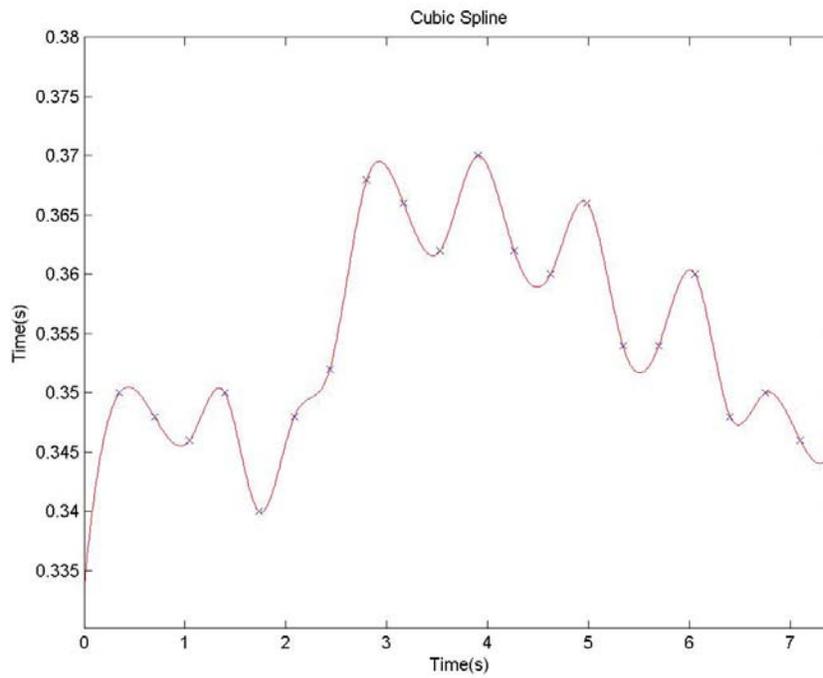

Figure 5-14. Cubic Spline Interpolation

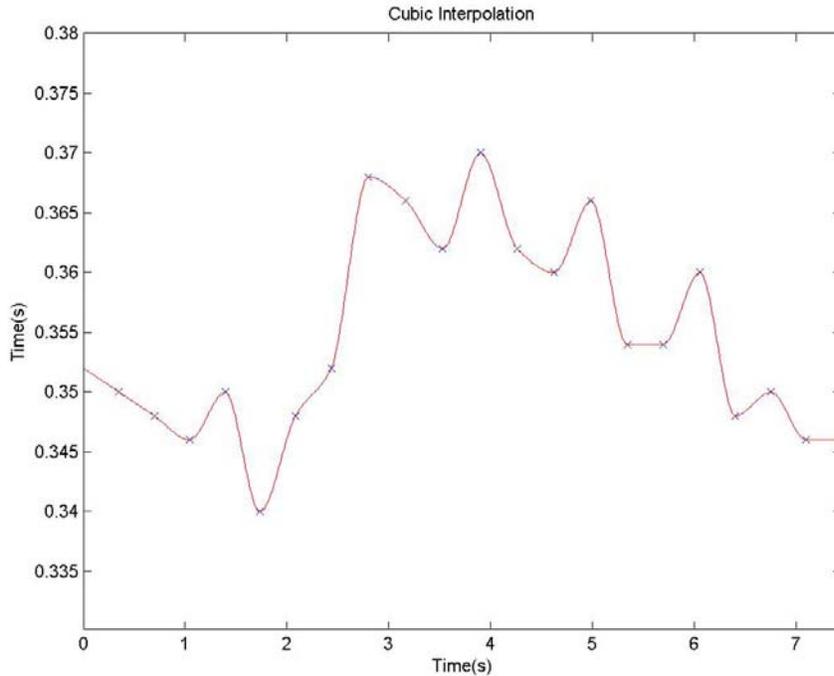

Figure 5-15. Cubic Interpolation

The performance of the interpolation techniques is shown applied to a sample RRI dataset marked by X's in the figures above. LI is continuous, but the slope changes at the vertex points. LPI has an adjustable order of polynomial and reduces to LI when the order equals one. As seen above, the LPI algorithm does not perform well at the endpoints. CSI produces the smoothest results of all the interpolation methods, but performs poorly if the data is highly non-uniform. CI results in both the interpolated data and its derivative being continuous. The CI technique seems the most realistic interpolation method because it does not force a sinusoidal interpolation. Therefore, we will use CI to interpolate and resample RRI in preparation for spectral analysis. It is necessary to resample the RRI at a frequency where the Nyquist rate is above the frequency range of interest for spectral analysis, discussed further in Chapter 6. Also in

Chapter 6, spectral analysis techniques will be introduced that do not require resampling of the RRi waveform prior examining HRV in the frequency domain.

CHAPTER 6 STATISTICAL ANALYSIS

Time Based

The simplest methods used to evaluate HRV are based in the time domain. Time domain statistics can be divided into those derived from RRi or iHR and those derived from differences in RRi, namely ΔRRi [26]. The following time-domain techniques will be used:

- Mean RRi (mRRi)
- Median RRi (medRRi)
- Standard deviation of RR interval (SDRR)
- Poincaré plots
- Quadrant analysis

First Order Statistics

Analysis of mRRi and medRRi yields some useful information about HRV. We will use this information to analyze trends of the mRRi and medRRi with gestational age and across genders. Also, the mRRi for the 45-s prestimulus period will be subtracted from each heartbeat of the 45-s prestimulus and stimulus period. The result will be a string of difference scores. The difference scores will be used to confirm that no significant HRV trending has occurred during the prestimulus period, which may mask or falsely demonstrate a COR. During the stimulus period, the difference scores will be used to detect an orienting response. The mRRi is calculated in the following manner:

$$mRRi = \frac{\sum_{n=1}^N RRi(n)}{N}$$

for N= number of RRI

To find the median, we must first sort the RR intervals by ascending values. Then, apply the following formula to find $medRRI$:

$$medRRI = RRI_{sorted}(N/2)$$

for even values of N

$$medRRI = \frac{RRI_{sorted}([N-1]/2) + RRI_{sorted}([N+1]/2)}{2}$$

for odd values of N

SDRR is highly dependant upon the length of the recording [26]. When using this value as a comparison across datasets, we must be careful to uniformly define the length of the recording. Therefore, we have kept all window lengths constant from subject-to-subject and session-to-session. The variance (SDRR squared) is mathematically equal to the total power of the spectrum; therefore SDRR will also be used to analyze trends corresponding to increasing gestational age. SDRR is the primary first order statistical analysis method we will use to discuss HRV in the time domain. SDRR is calculated in the following manner:

$$SDRR = \sqrt{\frac{\sum_{n=1}^N (RRI(n) - mRRI)^2}{(N-1)}}$$

where N= number of RRI

Poincaré Plots

In addition to numerical analysis in the time domain, the importance of geometric representations, such as Poincaré plots are useful tools for HRV analysis [26,27]. The nonlinear Poincaré plot produces a figure with each RRI plotted against the previous RRI.

According to Brennan et al., the plot provides summary information as well as detailed beat-to-beat information on the behavior of the heart. The dispersion of points perpendicular to the line of identity reflects the level of short-term variability [27].

In subjects with normal cardiac function, the geometry of Poincaré plots tends to be elliptical in nature. No literature pertaining to analysis of Poincaré plots using an ellipse were found, but we will explore an ellipse fitting method as a possible representation of short-term and long-term variability. MATLAB code written by Marcos Duarte [28] will be used to fit an ellipse to the data. Duarte calculates the major and minor axis of the ellipse using principal component analysis (PCA). The method results in 85.35% of the datapoints lying inside of the ellipse. The datapoints that fall outside the ellipse can be described by increasing the order of the ellipsoid, but it is only necessary to include the first two eigenvalues when analyzing the short and long-term variability of the dataset.

PCA is a multivariate procedure, which rotates the data such that maximum variabilities are projected onto the axes. Essentially through computing the eigenvalues of the correlation matrix, a set of correlated variables are transformed into a set of uncorrelated variables, which are ordered by reducing variability. The uncorrelated variables are linear combinations of the original variables, and the last of these variables can be removed with minimum loss of real data. The largest eigenvalue corresponds to the principal component in the direction of greatest variance; the next largest eigenvalue corresponds to the principal component in the perpendicular direction of next greatest variance.

PCA can be viewed as a rotation of the existing axes to new positions in the space defined by the original variables. In this new rotation, there will be no correlation

between the new variables defined by the rotation. The first new variable contains the maximum amount of variation. The second new variable contains the maximum amount of variation unexplained by, and orthogonal to, the first. The result is an ellipsoid in multidimensional space and reduces to an ellipse for the two dimensional Poincaré Plot.

When a Gaussian random vector has covariance matrix that is not diagonal, the axes of the resulting ellipse are perpendicular to each other, but are not parallel to the coordinate axes. As shown in the Figure 6-1, the principal components of the RR interval Poincaré representation result in an ellipse whose axes are rotated versions of the coordinate axes. Therefore, as discussed in Chapter 5, the assumption that a Normal distribution can describe RRi datasets is valid. The minor axis of the ellipse serves as an interpretation of short-term variability; and the major axis serves as an index on long-term variability.

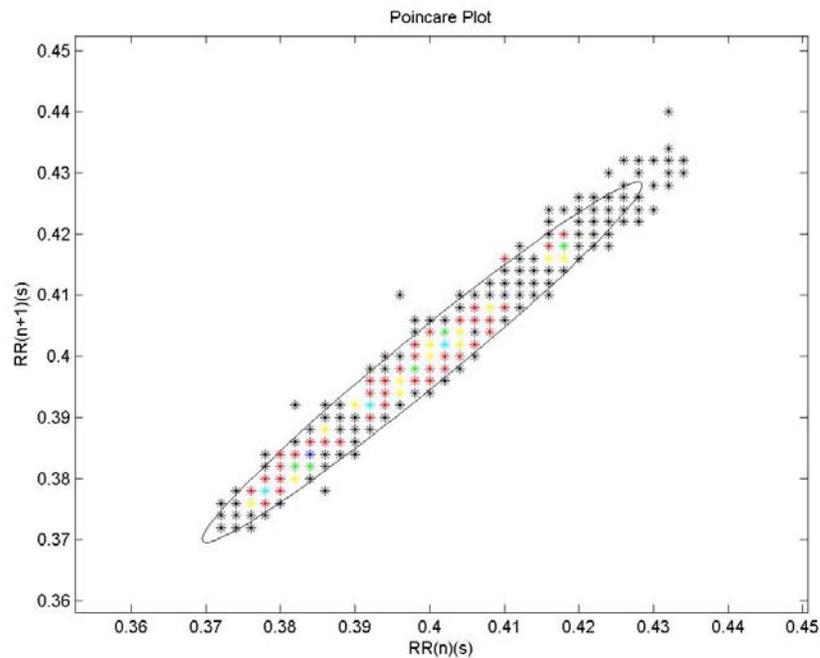

Figure 6-1. Poincaré plot representation of RRi. Since data points overlap, colors, coordinated with the visible spectrum, are used to indicate magnitude at each point.

Quadrant Analysis

Quadrant analysis is a graphical tool used to represent the number of sustained increases, sustained decreases, and alternating changes in RRI. Two vectors are created as follows:

$$\Delta RRI(n) = RRI(n) - RRI(n-1)$$

$$\Delta RRI(n+1) = RRI(n+1) - RRI(n)$$

Each difference value was then plotted against the previous difference, resulting in the $\Delta RRI(n)$ versus $\Delta RRI(n+1)$ plot shown below [4]. The plot displays values distributed over an area defined by four quadrants. Each quadrant indicates the direction of two consecutive changes in interval length.

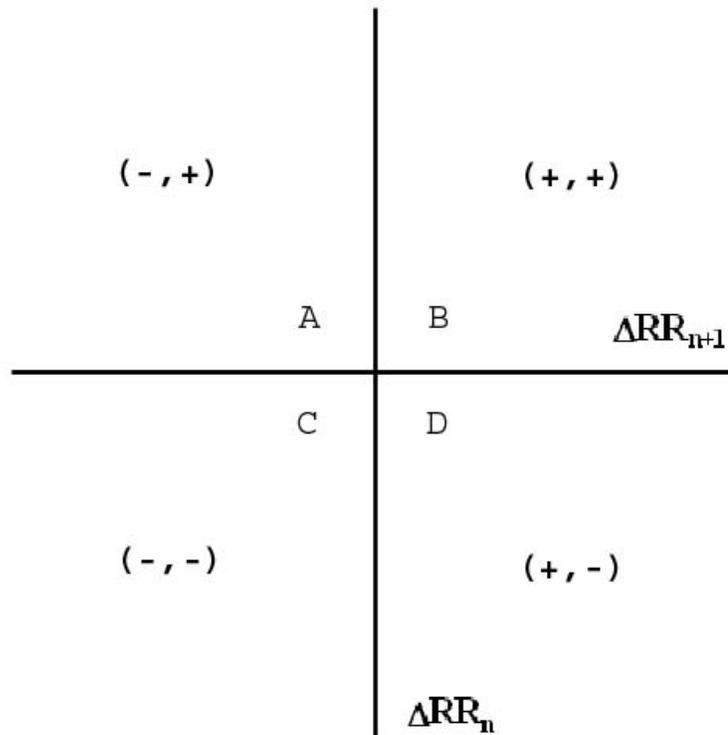

Figure 6-2. Defines the quadrants used in Quadrant Analysis.

We will use this analysis tool to examine sustained increases or decreases of RRI and alternating RRI. The number of points in quadrants A and D measure high frequency variation, or quick changes in RRI. Low frequency heart rate variation is characterized by many sequential increases and decreases in interval length, which is indicated by points in quadrants B and C. If changes in RRI occurred randomly and independently, all quadrants would have an approximately equal number of data points. In addition, if the heart rate tended to increase quickly and decrease slowly, more points would fall in quadrants A and B than in C and D and *visa versa*. Figure 6-3 is an example of a quadrant analysis plot extract from real RRI data.

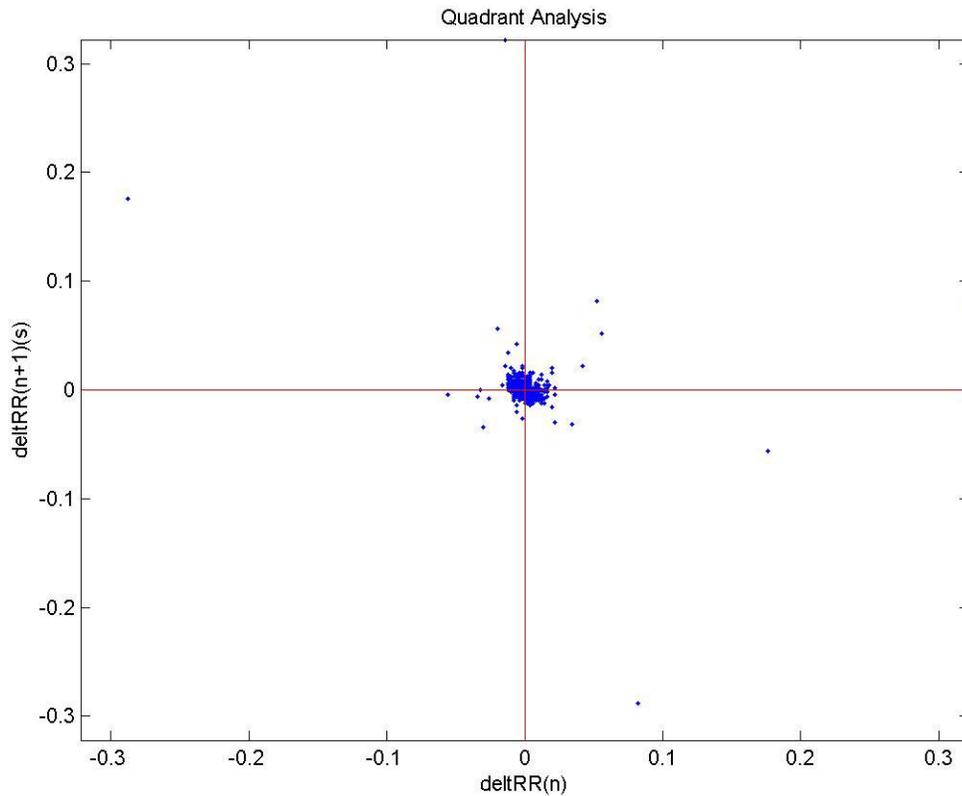

Figure 6-3. Example of Quadrant Analysis applied to an RRI dataset.

Frequency Based

While analytical methods were first restricted to the time domain, they have quickly shifted to the frequency domain. Spectral analysis is now a common representation of HRV. Transforming HRV to the frequency domain provides a means of separating the parasympathetic and sympathetic responses of the ANS. Heart rate fluctuations in the premature will be examined in the .00033-1Hz, while the frequencies below this will be discarded to reduce the influence of slow trends or artifacts. Research has suggested that the power spectral decomposition of the ECG yields frequency bands essential to analysis of the ANS. These frequency bands are very inconsistent throughout the literature referenced for this subject. This thesis will follow the frequency divisions described by Stein et al. [29]:

- The ultra low frequency band (ULFB) - $<.0033\text{Hz}$
- The very low frequency band (VLFB) - $0.0033 - 0.04\text{Hz}$
- The low frequency band (LFB) - $0.04 - 0.15\text{Hz}$
- The high frequency band (HFB) - $0.15 - 0.4\text{Hz}$
- The total power (TP) - $.0033 - 1\text{Hz}$

The low frequency band of the power spectrum is composed of two peaks. The mid-range peak ($.09 - .15\text{Hz}$) corresponds to the Mayer waves, which have been related to the baroreceptor reflex [3]. In addition, there exist a second peak between $.02 - .09\text{Hz}$, which has been linked to thermoregulatory fluctuations and variations in vasomotor tone. The high-frequency band reflects the parasympathetic response, while the low frequency band is influenced by the PNS and SNS [3]. For each frequency band listed above, we will extract the normalized power over the described range. Also, the power ratio of the

high and low frequency bands has been assumed to reflect the sympathovagal balance [3]. This power ratio is observed as follows:

$$SV_{ratio} = \frac{LFP}{(LFP + HFP)}$$

The SV ratio should provide us with insight into the ANS balance and should trend downward in accordance with increasing gestational age. Lastly, a range just above the high-frequency band contains information regarding the RSA, which is not represented by a well-defined peak, but is usually centered about the .5-.6Hz range. We will explore three methods of power spectral analysis in the following subsections:

- Fast Fourier Spectral Analysis
- Lomb-Scargle Spectral Analysis
- Empirical Mode Decomposition

Fast Fourier Spectral Analysis

The simplest and most commonly exploited technique for spectral analysis is the Fast Fourier Transform (FFT). The FFT is commonly used because it is computationally simple algorithm for spectral analysis. Fourier analysis decomposes a time-series into global sinusoidal components with fixed amplitudes. As a result, Fourier spectral analysis is limited to systems that are linear and strictly stationary. However, a high number of variables affect the heart rate, which suggests that an RRi signal is highly nonlinear and non-stationary. Most research pertaining to HRV utilizes the FFT to describe to the spectral components of the RRi signal. We will utilize the FFT spectral analysis method to obtain results, which can be compared with past and future research.

The FFT is computed using the internal FFT function provided by MATLAB. Since the FFT method is commonly used in signal processing, we will not discuss this

method in detail, rather we will explain how we computed the transform. All RRI windows for the RRI dataset (developmental, prestimulus, stimulus, and poststimulus) are analyzed separately based on a N-point FFT, where N is equal to the total number of point in the intervals. Often FFT windows are padded with zeros or with repeated copies of the window. Neither of these techniques adds any information to the resulting FFT. Padding only serves to increase the resolution of the transformation. Setting N to the length to the window abolishes the need for padding. Each of the aforementioned windows is extracted from the original recording based on cumulative time, and the resulting windows are unevenly sampled signals. The cubic spline interpolation technique, described in Chapter 5, is applied before computing the FFT and resampling the interpolated signal at 4Hz. We chose 4Hz to prevent aliasing above of the Nyquist frequency (2Hz) from falling into the frequency bands of interest. Finally, the resampled signal is passed through the FFT algorithm and the DC component of the FFT transformation vector is removed by dropping the first term. Results from this algorithm can be found in the following chapter.

Lomb Spectral Analysis

In order to avoid the consequence of interpolation, we explore the Lomb method to estimate the power spectral density (PSD) of unevenly sampled signals. Laguna et al. concluded that for PSD of these unevenly sampled signals the Lomb method is more suitable than FFT estimates requiring linear or cubic interpolation [30]. The Lomb estimate avoids the low pass effect of resampling and avoids aliasing up to the mean Nyquist frequency:

$$\mu_{Nf} = \frac{1}{(2 * mRR)}$$

The Lomb method is based on the minimization of the squared differences between the projection of the signal onto the basis function and the signal under study [30].

$$x(t_n) + \varepsilon_n = c(i)b_i(t_n)$$

Minimizing the variance of ε_n (mean squared error), is synonymous to the minimization of

$$\sum_{n=1}^N |x(t_n) - c(i)b_i(t_n)|^2$$

which results in [30]

$$c(i) = \frac{1}{k} \sum_{n=1}^N x(t_n)b_i^*(t_n) \quad k = \sum_{n=1}^N |b_i(t_n)|^2$$

In addition, the signal power at index i of the transformation as described by Lomb [31]:

$$P_x(i) = c(i) \sum_{n=1}^N x^*(t_n)b_i(t_n) = k * |c(i)|^2 = |\hat{c}(i)|^2 \quad \text{where } \hat{c}(i) = c(i)\sqrt{k}$$

Setting the basis function to that of the Fourier transform

$$b_i(t_n) = e^{j2\pi f_i t_n}$$

Then,

$$k = \sum_{n=1}^N |e^{j2\pi f_i t_n}|^2 = N$$

And

$$P_x(i) = P_x(f) = \hat{c}^2(f)$$

Lomb presented a simplification that permits one to solve for each coefficient independently, known as the Lomb normalized periodogram. First, we solve for the mean and variance [31]:

$$\bar{x} = mRR$$

$$\sigma^2 = (SDRR)^2$$

Then, we generate the Lomb normalized periodogram using the i^{th} angular frequency

$$P_X(\omega_i) = \frac{1}{2\sigma^2} \left\{ \frac{\left[\sum_{n=1}^N (x(t_n) - \bar{x}) \cos(\omega_i(t_n - \tau_i)) \right]^2}{\sum_{n=1}^N \cos^2(\omega_i(t_n - \tau_i))} + \frac{\left[\sum_{n=1}^N (x(t_n) - \bar{x}) \sin(\omega_i(t_n - \tau_i)) \right]^2}{\sum_{n=1}^N \sin^2(\omega_i(t_n - \tau_i))} \right\}$$

where τ_i is defined as,

$$\tau_i = \frac{1}{2\omega_i} \arctan \left[\frac{\sum_{n=1}^N \sin(2\omega_i t_n)}{\sum_{n=1}^N \cos(2\omega_i t_n)} \right]$$

MATLAB code written by David Glover is used to compute this Lomb normalized periodogram [32]. We apply this method of spectral analysis to the identical windows used to compute the Fourier PSD; and we will compare the results in the following chapter.

Empirical Mode Decomposition

Approximations are the key to understanding complex natural phenomena and often there is a significant advantage to these methods. However, science is continuing to develop ways to describing complex system and behaviors. Why approximate the RRi signal as a linear, stationary signal when tools exist to analyze nonstationary, nonlinear systems? The answer is rhetorical because the only reason describes the simplicity of the computation of the FFT. Given all the assumptions needed to compute the FFT, it is necessary to search for a more reliable spectral transformation. We have already observed the Lomb method, which still assumes the signal is linear and stationary. Now,

using a technique developed by Haung et al. [33], this thesis will compare the effectiveness of the Empirical Mode Decomposition (EMD) as an analysis tool of HRV.

The goal of EMD is to decompose a time series into superposition of Intrinsic Mode Functions (IMF). EMD uses a sifting process to produce IMFs, which enables complicated data to be reduced into a form with defined instantaneous frequencies. The IMFs has the appearance of a generalized Fourier analysis, but with variable amplitudes and frequencies. Haung et al. describes EMD as the first local and adaptive method in frequency time analysis. Furthermore, Haung suggests that the advantage of EMD and Hilbert spectral analysis is that it gives the best-fit local sine or cosine form to the local data. The frequency resolution for any point is uniformly defined by the local phase method and is especially effective in extracting low frequencies oscillations [33]. Since the HRV is characterized by low frequency oscillations, this method should produce informative frequency domain representation of HRV.

Computation of the EMD algorithm is done in MATLAB using modified code originally written by G. Rilling [34]. The EMD algorithm [33] coded by Rilling begins with the sifting process. First, all local extrema of the original signal are identified. The local maxima are then connected via a cubic spline and the procedure is repeated for the local minima, respectively forming the upper and lower envelopes. Then, we find the first component of the sifting process [33], h_1 .

$$h_0 = X(t) = RRi(t)$$

$$h_1 = h_0 - m_1$$

where m_1 is the mean of the envelope

The shift process is repeated k times, as follows, until h_{1k} is an IMF (c_1).

$$h_{1k} = h_{1(k-1)} - m_{1k}$$

$$c_1 = h_{1k}$$

Then, a residual is found

$$r_1 = X(t) - c_1$$

Finally the IMF procedure is repeated n times until the residual, r_n , is a trend or constant.

$$r_n = h_{(n-1)} - c_{(n+1)}$$

It is then necessary to determine if all the calculated IMF are actually orthogonal to one another, as the theory suggests. Huang suggests using the follow equation as a check for orthogonality [33]:

$$IO_{fg} = \sum \frac{c_f c_g}{c_f^2 + c_g^2} \approx 0 \quad \text{for all IMFs}$$

In order to visualize the result of EMD, we must find the Hilbert transforms of the IMF components and represent the RRi signal in terms of time, frequency, and amplitude. We compute the Hilbert transforms using the Cauchy principal value integral to find the magnitude, $a_n(t)$, and phase, $\theta_n(t)$, and instantaneous frequencies, ω_n [33].

$$Y_j(t) = \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{c_j(t')}{t-t'} dt'$$

$$Z_j(t) = X_j(t) + iY_j(t) = a_j(t) e^{i\theta_j(t)}$$

$$a_j(t) = \sqrt{X_j^2(t) + Y_j^2(t)}$$

$$\theta_j(t) = \arctan\left(\frac{Y_j(t)}{X_j(t)}\right)$$

$$\omega_j = \frac{\partial\theta(t)}{\partial t}$$

Finally, we can express the RRi dataset as follows

$$RRi(t) = \sum_{j=1}^n a_j(t) \exp[i \int \omega_j(t) dt]$$

Clearly, the equation above represents the generalized Fourier expansion, but the amplitude and instantaneous frequency are variable with respect to time [33]. At this point, we will use the EMD method to provide us with a visual representation of the power spectrum changes over a prestimulus → stimulus → poststimulus window. In accordance with the description of a COR, detailed in Chapter 2, we should see significant shift in the magnitude of frequency spectrum over this window.

Statistical Analysis of Parameters

Statistical analysis of the parameters extracted above is performed using a technique for longitudinal data analysis, called mixed general linear models (MixMod) or random regression models [35]. The MixMod model allows the concurrent identification of both group and individual patterns in longitudinal sets with covariates that vary over time, inconsistently timed data, irregularly timed data, and randomly missed values. Given the vulnerable state of the infants in the NICU, we must perform test sessions in accordance with the health status of the infant. These stability considerations can result in the testing schedules varying from subject to subject and session to session. Fortunately, problems arising from this effect are alleviated using the MixMod analysis. In addition, subjects are often transferred or released before reaching 34 weeks GA. The MixMod model allows us to include the data from these subjects, thereby reducing the amount of data, which would otherwise be lost. Strengths of the MixMod model include the acceptance of multiple characteristics and the exploration of patterns across subjects and groups. Using multiple characteristics, MixMod leaves the statistical correlation and inclusive of parameters up to the investigator [35]. All MixMod analysis is performed by

Dr. Kruger using readily available SAS Proc Mixed software. The results of the MixMod analysis can be found in the Clinical Results section of Chapter 7.

CHAPTER 7 DISCUSSION AND RESULTS

Engineering Results

We will explore the results of the signal-processing phase of this thesis in accordance with ECG recordings from one subject. The example subject is not intended to prove the clinical significance of the hypothesis described in Chapter 3. For clinical evaluation of aforementioned hypotheses, please refer to the “Clinical Results” subsection of this chapter.

QRS Detection Algorithm

The following table is a representation of the performance of the QRS detection algorithm, detailed in Chapter 5. The percent of QRS complexes is computed, as follows,

$$QRS_{\text{detected}} = \frac{\#_{\text{detections}}}{(\#_{\text{detections}} + \#_{\text{missed}})}$$

where the interpolated detections are tagged as missed detections and are stored in a separate array to determine the QRS detection ratio defined above. The interpolations are a result of no detected QRS complexes falling within the user defined expectancy range, described in Chapter 5.

Table 7-1 clearly illustrates that on average the algorithm only misses 0.85% of the QRS complexes in the signal. This detection algorithm is a robust system, which can effectively detected QRS complexes in the presence of noise and muscle artifact and produce reliable RRi datasets. Beyond the detection process, we improve quality of the

RRi signal through the implementation of the outliers removal algorithm designed in Chapter 5.

Table 7-1. Shows the performance of the QRS detection algorithm

Patient	Recording Number	QRS detections (%)
3	12130842	99.25

HRV Plots and Statistics

Scientific findings are based on equally important qualitative and quantitative measures. Quantitative methods observe distinguishing characteristics and elemental properties resulting in numerical comparative analyses and statistical analyses. For each recording, an excel file is created, which contains all the pertinent quantitative measures for each window:

- mRR
- medRR
- SDRR
- Number of sustained increase and decreases in HR derived through Quadrant Analysis
- The length, width, and (W/L) ratio of the PCA fit elliptical representation of the Poincaré plot
- ULF, VLF, LF, and HF power of the Lomb PSD
- TP and SV_{ratio} of Lomb PSD
- ULF, VLF, LF, and HF power of the Fourier PSD
- TP and SV_{ratio} of Fourier PSD

These quantitative measures are used for MixMod analysis in the “Clinical Results” section.

Qualitative measures are those associated with interpretative approaches, from the investigators point of view, rather than discrete observations. While qualitative methodologies can lead to biased results, there is no doubt that they should be included in medical research. The power of visualization and quick interpretation of data possessed by humans cannot be replaced by quantitative measures. Therefore, for each recording, six plots are created for qualitative analysis:

- HR with outlier removal
- Quadrant analysis
- Poincaré
- Fourier PSD
- Lomb PSD
- Hilbert-Huang spectrum of EMD

HR Plot

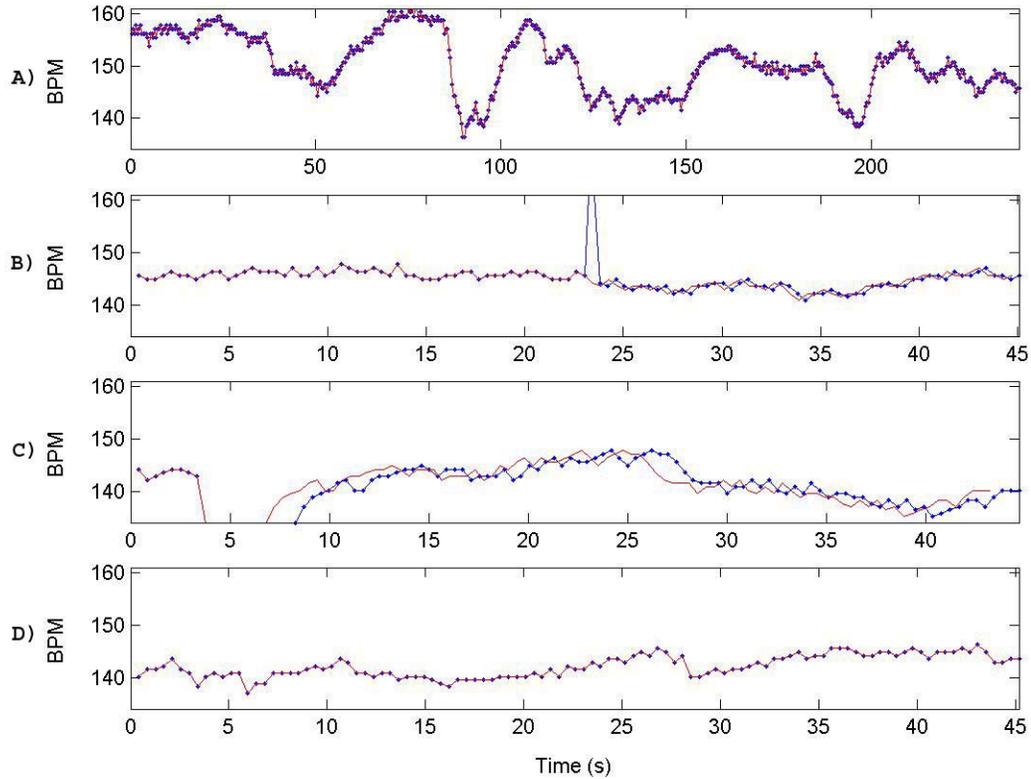

Figure 7-1. HR plots of example RRI data. From top to bottom they represent: the (a) developmental, (b) prestimulus, (c) stimulus, and (d) poststimulus periods.

The HR plot shown above illustrates the original RRI (blue) waveform displayed as instantaneous heart rates and the resulting RRI (red) after outliers have been removed. The figure above is divided into four plots representing the four windows of analysis. Plot (b) illustrates the removal of an outlier, which causes a high frequency spike in the signal. Plot (a) demonstrated the algorithm efficiency of preserving trends in RR intervals. Figure 7-1 is used to visualize cardiac accelerations and decelerations, quantitatively described through Quadrant Analysis.

Quadrant Plot

The Quadrant plot shown in Figure 7-2, below, is organized in the same manner as Figure 7-1 with each plot representing a particular analysis window. Quadrant Analysis is a more useful tool for quantitative analysis, but the visual representation can provide insight into the amount of high and low frequency variability. The excel file described above contains some useful information regarding this plot that will later be used for MixMod analysis.

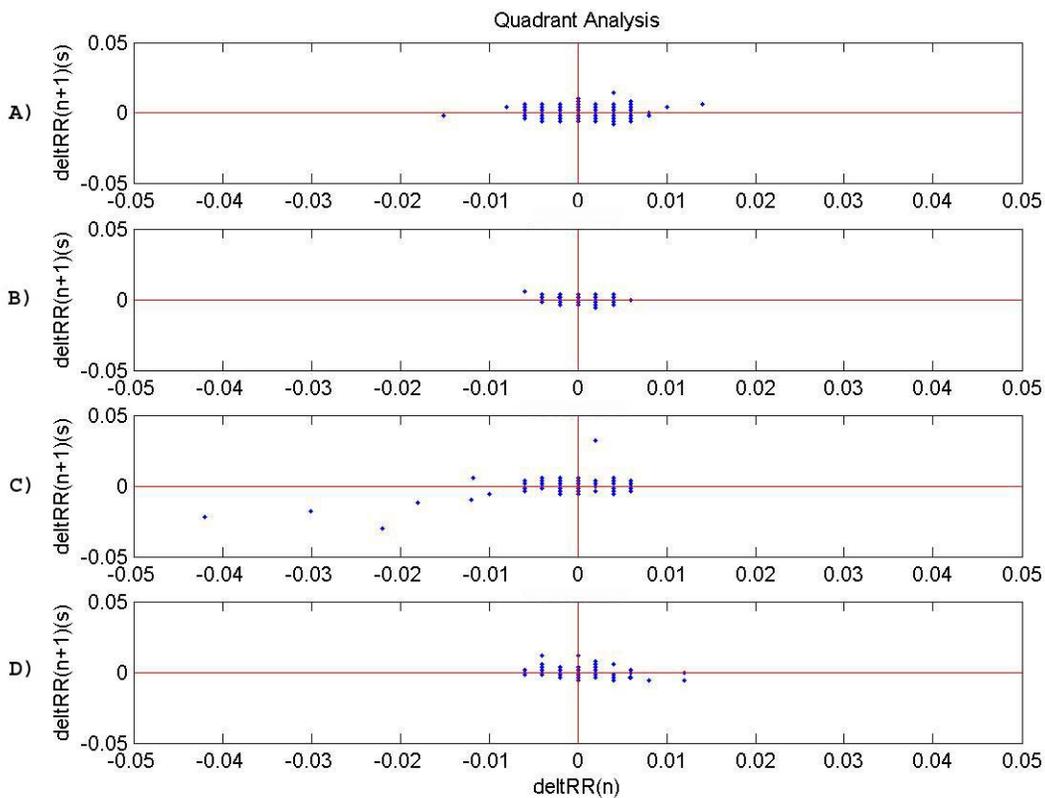

Figure 7-2. Quadrant Analysis plots of example RRI data. From top to bottom they represent: the (a) developmental, (b) prestimulus, (c) stimulus, and (d) poststimulus periods.

Poincare Plot

The Poincare plot is a valuable tool for both quantitative and qualitative analysis. The Poincaré method of RRi interpretation is observed to prove normal cardiac function and analytically evaluated by the fitted ellipse to described short and long-term HRV.

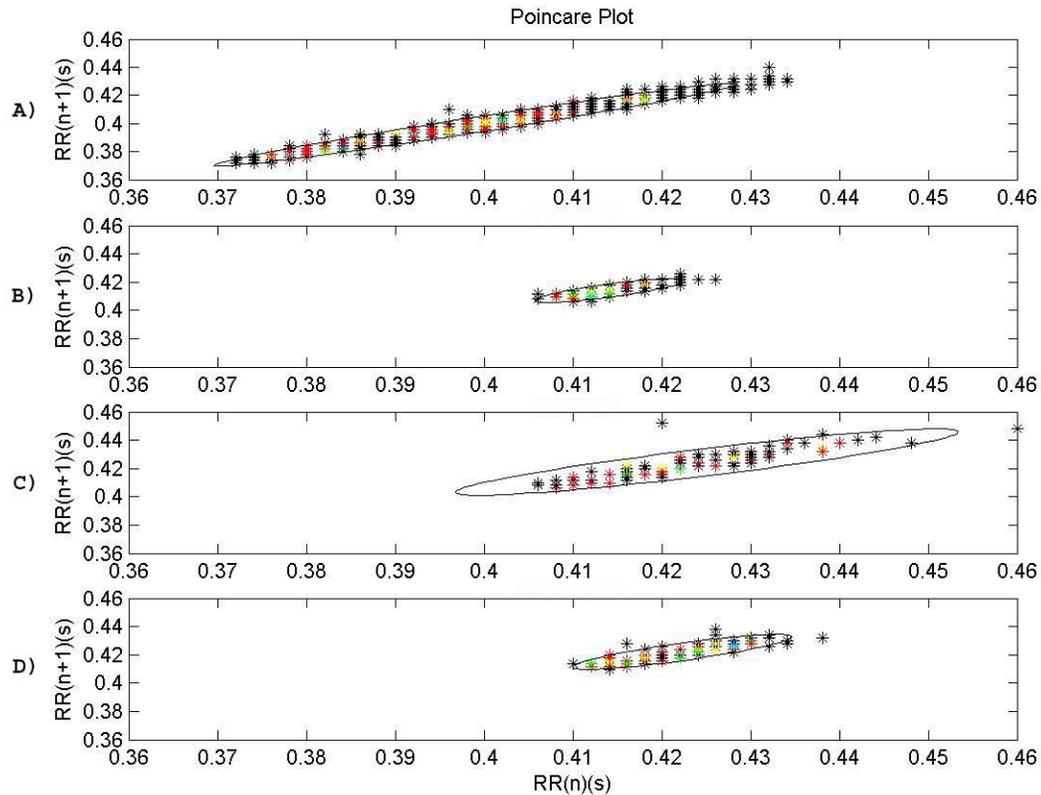

Figure 7-3. Poincaré plots of example RRi data. From top to bottom they represent: the (a) developmental, (b) prestimulus, (c) stimulus, and (d) poststimulus periods.

Again the magnitude corresponding of a given point is represented by the basic colors of the visible light spectrum with red being the next to least frequent (black is the least) and violet being the most frequent. Plot (a) represents the dataset with the most long-term variability or low-frequency changes inferred by the length of the major axis of the ellipse. This is expected because plot (a) is a 240s window, while plots (a,b,c) are 45s

windows. We can also see that during the stimulus period the major and minor axis of the ellipse become significantly longer, perhaps signifying an increase the LF power, HF power, and total power of the HRV spectrum. We will next look at the Fourier and Lomb PSD to confirm this hypothesis.

Fourier and Lomb Plots

The Fourier and Lomb PSD plots essentially describe the same information; therefore we will observe them together.

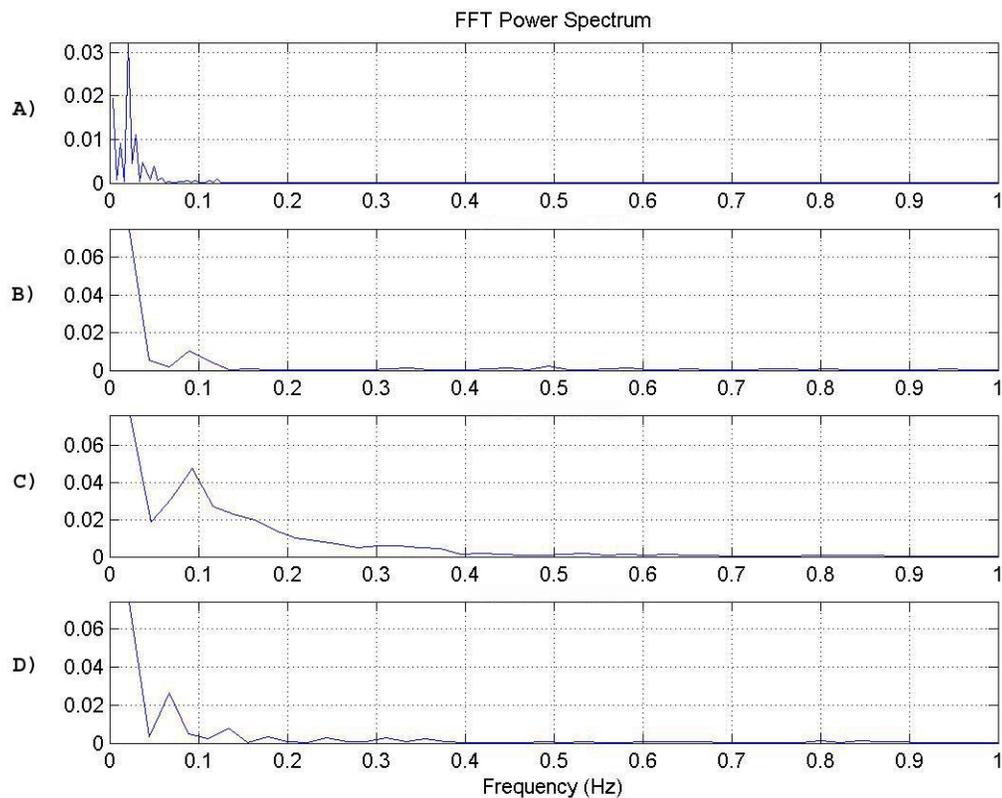

Figure 7-4. Fourier PSD plots of example RRi data. From top to bottom they represent: the (a) developmental, (b) prestimulus, (c) stimulus, and (d) poststimulus periods.

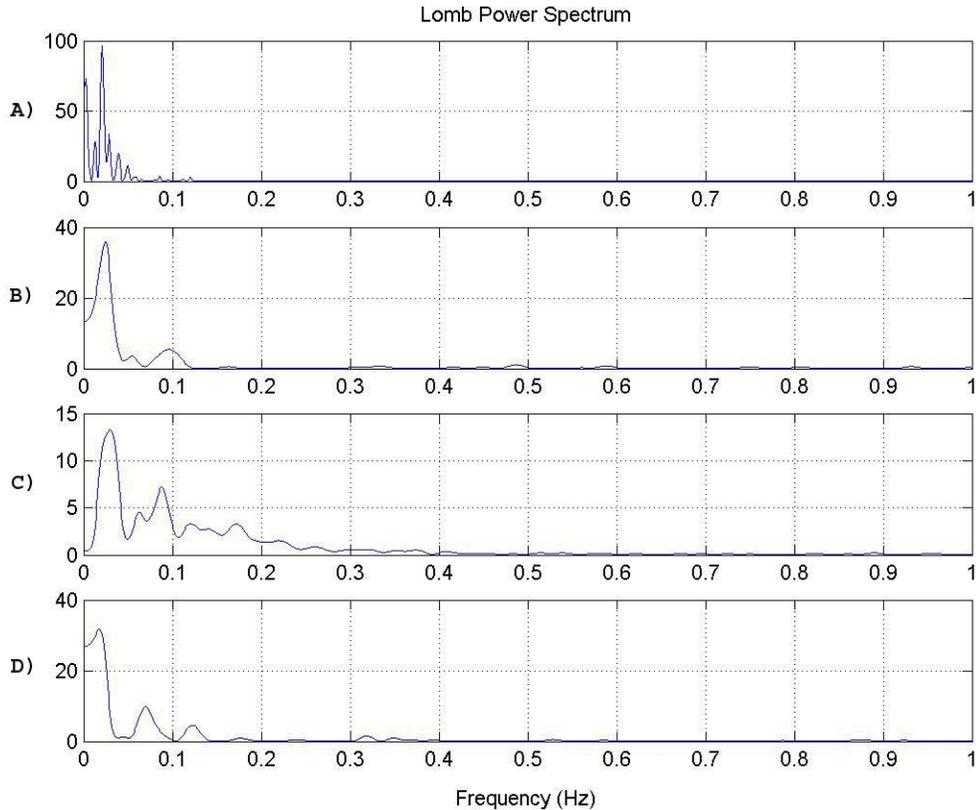

Figure 7-5. Lomb PSD plots of example RRi data. From top to bottom they represent: the (a) developmental, (b) prestimulus, (c) stimulus, and (d) poststimulus periods.

First, we will address the observational hypothesis from the Poincaré Plot section.

Inspecting the Fourier and Lomb stimulus plots, we note that the area under the curve increases from the prestimulus period to the stimulus period, which means there is an increase in total power. Also, power increases in the LF and HF bands correspond to increases in the length of the major and minor axes of the ellipse, respectively. In conclusion, through qualitative analysis, we have shown that the Poincaré plot is a time domain representation of the PSD.

Now we will compare the PSD representations of the Fourier and Lomb Spectrum. The Fourier and Lomb plots are comparable over the developmental window,

but the Fourier plot is choppier than the Lomb plot over the windows corresponding to the COR. The choppy Fourier plot is a result of the low frequency resolution of the N -point Fourier transformation. Therefore, the frequency resolution is lower for the short windows analyzed in plots b, c, and d. However, the Lomb computation allows the user to set the frequency resolution. For the purpose of obtaining a smooth transformation, we have set the Lomb PSD resolution to 0.001Hz. To increase the frequency resolution of the FFT, we must pad the data before performing the Fourier transform. For reasons discussed in Chapter 6, we have refrained from doing so. The apparent equivalent Lomb and Fourier PSD plots for the developmental window suggest that the Lomb method is at least as successful as the Fourier for PSD estimation. For clinical interpretation, we will use the Lomb Spectrum when computing the cumulative power in the frequency bands of interest.

EMD Plots

At this point, we use the Hilbert-Huang Spectrum (HHS) only as a qualitative analysis tool. If the clinical findings indicate the usefulness of this time-frequency domain representation of HRV, we will expand to use EMD as a quantitative analysis tool. Figure 7-6 is the HHS of the example RRi dataset used in this section. Black lines separate the prestimulus, stimulus, and poststimulus periods. We can relate the HHS power shift of the stimulus period to those described by the Poincaré and PSD assessments of HRV. All four representations are in agreement that during the stimulus period the LF power, HF power, and TP increase. However, the HHS shows us that this increase occurs just after the rhyme begins only to tail-off significantly shortly thereafter. Initially the EMD seems to be a robust method to describe the HRV characteristics of the COR with respect to time. However, since this method has not often been used for

clinical interpretation, the inclusion of the method in the analysis of the hypothesized COR will be left up to the PI.

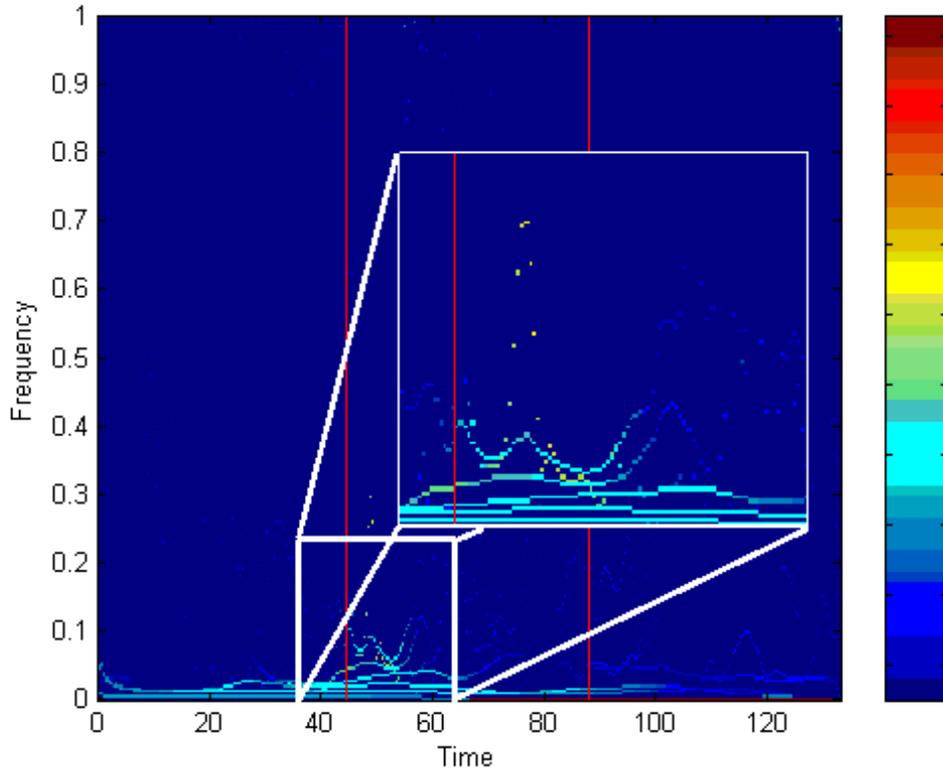

Figure 7-6. Hilbert-Huang spectrum of the COR windows of an example RRi dataset.

Clinical Results

At the time of submission, we only have four complete datasets (recordings for the 28-34 weeks GA) and one incomplete dataset (recordings for 28-33 weeks GA) that can be used for clinical interpretation. The current sample size ($n=5$) is well below the minimum sample size ($n=28$) described in the design of this study [7]. Therefore, we will not be able to perform MixMod analysis of the data at this time. Instead, we will use a repeated measures ANOVA analysis of the PSD. Repeated measure ANOVA allows us to compare the variance caused by the independent variables to a more accurate error term, which includes the variance effects of individual subjects. Thus, this method

requires fewer participants to yield an adequate interpretation of the data than the MixMod method.

Early analysis based on the Poincaré plots, Quadrant Analysis, and EMD will not be performed due to the lack of comparable literature. We will exploit the aforementioned methods upon completion of the study, so the PSD results can be used to confirm the clinical significance of these models. The repeated measure ANOVA model returned only two independent variables (HF power and SV power), which passed the equal variance test. We will first examine results of the repeated measures ANOVA analysis of the SV power defined in Chapter 6.

Table 7-2. Results of the repeated measures ANOVA with independent variable (SV power).

Session	n	μ	σ
1	5	0.807	0.0857
2	5	0.729	0.089
3	5	0.846	0.121
4	5	0.878	0.0501
5	5	0.742	0.239
6	5	0.866	0.0836
7	4	0.613	0.186

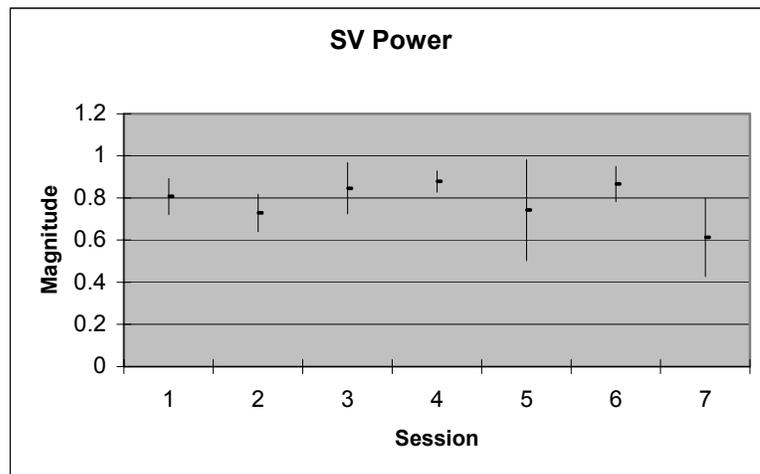

Figure 7-7. Plot of mean SV power with standard deviation bars across sessions

Now we examine repeated measures ANOVA analysis of the HF power, also defined in Chapter 6.

Table 7-3. Results of the repeated measures ANOVA with independent variable (HF power).

Session	n	μ	σ
1	5	68.2	25.925
2	5	133.6	144.921
3	5	48.46	26.837
4	5	41.32	23.877
5	5	178.1	172.465
6	5	47.22	58.952
7	4	150.75	126.818

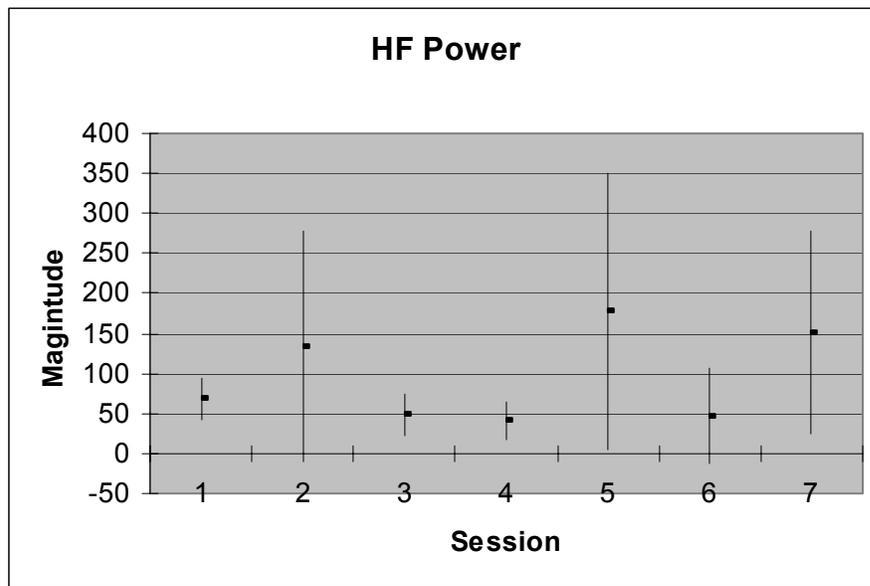

Figure 7-8. Plot of mean HF power with standard deviation bars across sessions

While Figure 7-7 shows a possible non-linear trend with respect to GA, Figure 7-8 does not elicit any significant trend in time. First, the small sample size doesn't allow for the development of a trend. Secondly, there exist many exogenous variables, which conceal a developing trend corresponding to GA. These variables include, but are not limited to:

- Drug interventions and interactions
- Respiratory support interventions
- Physiological discrepancies in ANS maturation
- Changes in NICU environment
- Incorrect evaluations in GA

Patient logs will be analyzed following the completion of the study for drug interventions. The PI will attempt to parallel the interventions with the recordings that contribute most to the standard deviation of each variable. It is known that certain drugs inhibit or even block parasympathetic and sympathetic responses. Furthermore, many of our subjects are on multiple drugs whose interactions with respect to the ANS are not known.

Many subjects intermittently require respiratory interventions such as continuous positive airway pressure (CPAP). A closed-loop study showed that adequate application of long-term CPAP therapy produced substantial alterations in the major physiological mechanisms that influence HRV and blood pressure variability [36]. Based upon preliminary results, see Figures 7-7 and 7-8, final results need to include an analysis of how drug and respiratory interventions hinder the ability to identify trends in the ANS landscape. The significance of all exogenous variables mentioned above will emerge as the number of subject in the dataset increases. Unfortunately, these results are not included in this thesis, but we refer you to further publications by the PI and the author of this paper. For a complete time and frequency domain analysis of a randomly selected subject, please refer to Appendix A and B, respectively.

CHAPTER 8 CONCLUSION

We have successfully modified code written by HP to communicate with the Agilent/HP NICU monitor. This program records the ECG, respiratory rate, and rhyme state in a text file at a 500 Hz sampling rate. The text file can be read into MATLAB for QRS detection and HRV analysis. In MATLAB, we have created an algorithm to perform accurate detection of QRS complexes. The average percentage of missed detections is approximately 0.8%, which we feel represents a near optimal detection algorithm. For those QRS complexes that are undetectable, we have constructed an interpolation method to replace the missing data. Using our novel method of tagging outliers, we are able to remove outliers, but preserve trends across time.

We have found that the most useful measurement of HRV in the time-domain is through the analysis of Poincaré plots. Fitting an ellipse to the Poincaré representation of the RRi is usefully in relating time-domain analysis to the frequency domain. Currently, most spectral representations described in literature use the Fourier transform. We have found that the Lomb normalized periodogram is a better representation of the power spectrum of RRi waveforms. The Lomb algorithm avoids the negative effects of interpolation and resampling required for FFT computation. Also, Empirical Mode Decomposition is a favorable method for measuring changes in the frequency spectrum across time. The EMD spectrum preserves more information regarding shifts in the frequency spectrum during the stimulus period than either the Lomb or Fourier spectrum. EMD has been proven to be a useful analysis tool to depict a COR.

We have discussed the importance of both qualitative and quantitative measures of developmental changes in HRV and in identifying a COR; we have extracted numerous features using time and frequency domain HRV analyses, which will be used to analyze and test the hypotheses of the clinical study still in progress. We feel we have completed the design phase of the study and need only to increase our sample size. As the sample size increases, the clinical significance of each feature will be evaluated and we will move to interpret our findings and test our hypotheses.

CHAPTER 9 FUTURE WORK

A need exists in the NICU and beyond to determine the state of development of the ANS. Before an infant is discharged from the NICU, it is important to determine their ability to perform certain life support tasks. In Chapter 2, these life-supporting tasks were linked to the maturity of the ANS, specifically the PNS. The list below is compiled from the 1998 suggested guidelines for neonatal discharge established by the American Academy of Pediatrics (AAP) [37]. In the judgment of the responsible physician there has been:

- A sustained pattern of weight gain of sufficient duration.
- Adequate maintenance of normal body temperature with the infant fully clothed in an open bed with normal ambient temperature (24°C to 25°C).
- Competent suckle feeding, breast or bottle, without cardiorespiratory compromise.
- Physiologically mature and stable cardiorespiratory function of sufficient duration.
- Appropriate immunizations have been administered.
- Appropriate metabolic screening has been performed.
- Hematologic status has been assessed and appropriate therapy instituted as indicated.
- Nutritional risks have been assessed and therapy and dietary modification instituted as indicated.
- Sensorineural assessments, hearing and funduscopy, have been completed as indicated.
- Review of hospital course has been completed, unresolved medical problems identified, and plans for treatment instituted as indicated.

The AAP has established these guidelines, which include subjective observations of cardiorespiratory function and sensorineural assessments. It is our hypothesis that cardiac function, as well as, neural assessments can be objectively realized using an index of ANS maturation. We will create this index of ANS functionality based on HRV comparisons with mature young adults. Below, we suggest a pilot study, which shall provide evidence that an index of maturation can be realized.

Record Baseline Adult HRV Data

In order to establish a baseline for a mature ANS with a synonymously high vagal tone, it is important to analyze the HRV of the young, healthy adult. ECG recordings will be obtained for a sample of 28 male and female adults meeting the following criteria:

- Between the ages of 18-30
- No history of congestive heart failure, myocardial infarction, coronary artery disease, head trauma, or diabetes
- Normal sinus ECG rhythm

The length of the recordings should be equal to those used in the study of the fetus. This is important we comparing both time and frequency domain features of HRV and the COR.

Each subject should be oriented in the supine position to ensure consistency with ECG recordings of the neonates. Before recording, all subjects should remain in this position without auditory and visual stimulation, until they are verified to be in REM or paradoxical sleep. Consistency with the neonatal recording described in the paper is a significant issue for accurate interpretation of HRV data and the adult period of REM sleep corresponds to the neonatal state of “active sleep” [38]. Siegel suggests that the phasic motor activation that characterizes REM sleep in the adult is also present in the

neonate. The amplitude of the twitching, described during REM sleep, is more intense in neonates than in the adult, but a developmental continuity can be observed between "active sleep" in the neonate and REM sleep in the adult.

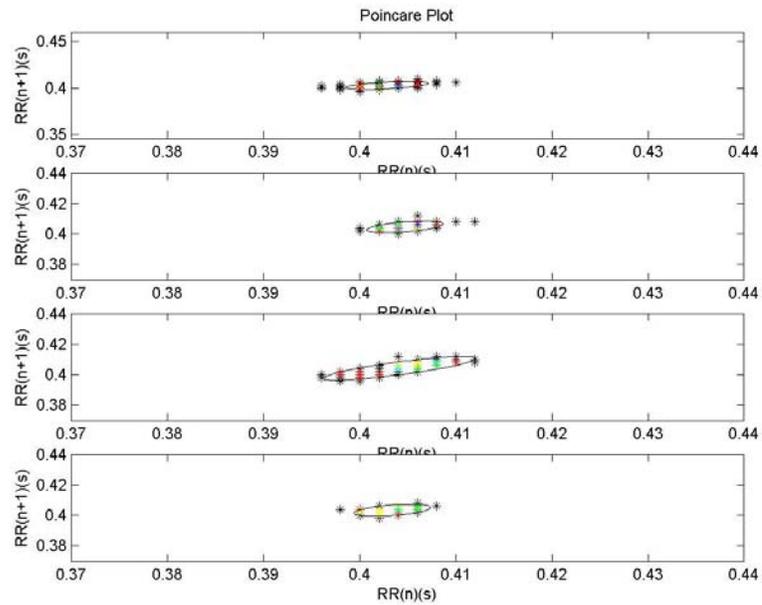

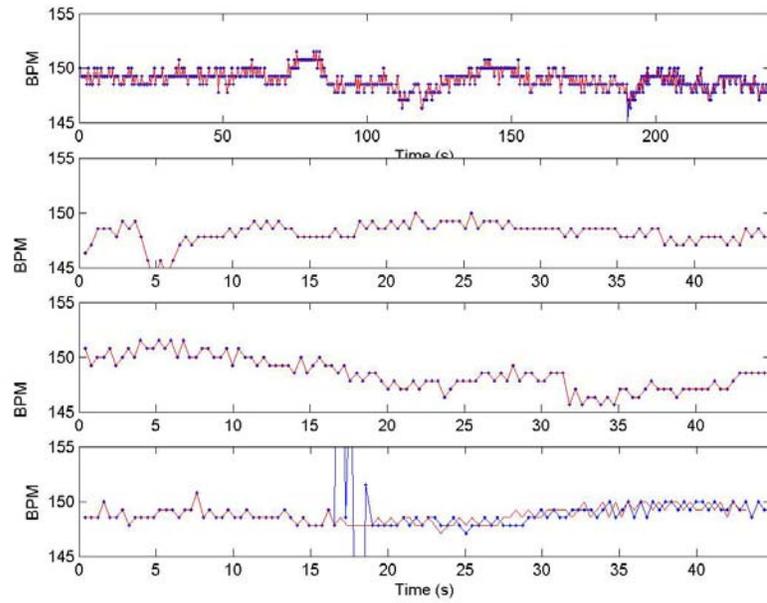

Both active sleep in the neonate and REM sleep in the adult can be defined by purely behavioral criteria [38]. Therefore, the recordings should be taken in the presence of a medical professional qualified to identify phases of paradoxical sleep. An auditory stimulation that is widely familiar and contains no political or nationalistic propaganda should be used to prevent to prevent undesirable neural responses due to stress. The ECG recordings during the auditory stimulation can later be used to compare the COR of the neonate and adult.

Creating the Index of ANS Maturation

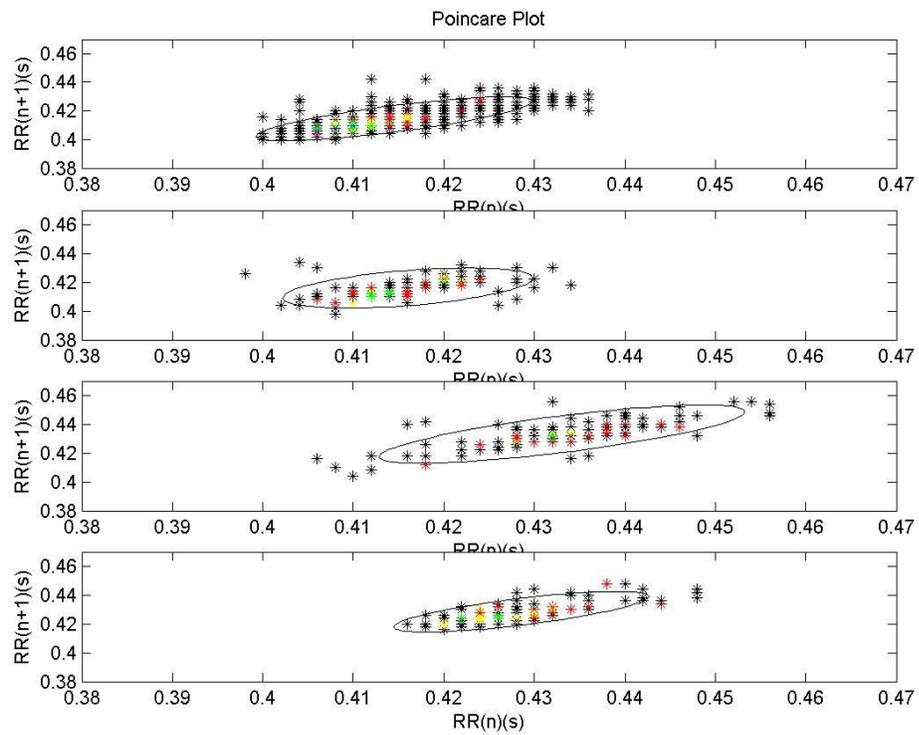

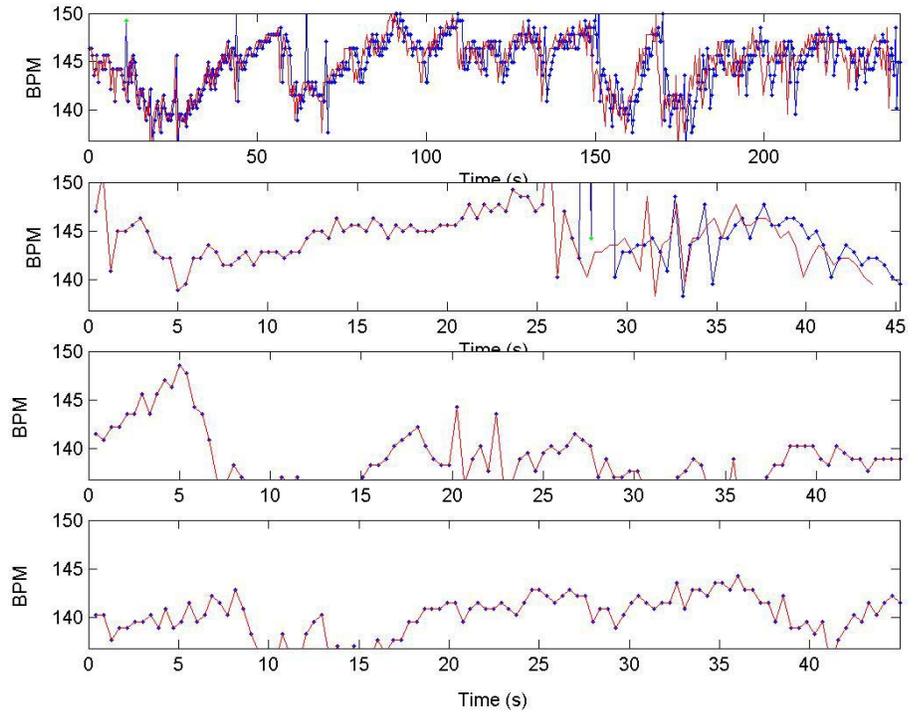

We suggest using the EMD method, detailed in Chapter 6, to compare the COR of the HRV groupings described in the previous subsection with the mature adult. The EMD data provides a time-based representation of the COR. The examiner should compare differences in the COR of the adult and neonate to determine an efficient method for relating these changes. We suggest exploring the use of power-ratios, neural networks, windowing functions, etc. as possible criteria to represent the EMD data in the form of an index. In addition, the development data can be compared using PCA and a neural network to classify the Lomb spectrum into different level of ANS maturation.

BIOGRAPHICAL SKETCH

Devin Lebrun received his bachelor's degree in electrical engineering with a focus in communications from the University of Florida in 2001. He received his Master of Engineering in electrical engineering from the University of Florida in August 2003. His research interests include biomedical imaging, digital signal processing, and neural networks.
